hollow-fiber FlFFF.[152,153] The observed decrease in retention time with increasing sample load for particles and charged polymers has been explained on the basis of excluded volume effects. For systems where the sample volume fraction is not negligible, λ values are expected to be higher than those predicted from standard FFF theory, which assumes infinitely small non-interacting species.[154] Since both the interparticle electrostatic repulsion and chain expansion due to intramolecular repulsion contribute to an increase in the effective volume occupied by the sample species, an enhanced overloading effect is expected for charged particles. In contrast, a depression of the phenomenon may be predicted with a reduction of the electrostatic effects. It follows that the ionic strength of the carrier liquid should considerably affect the onset of sample overloading. High ionic strength is expected to reduce both the overall molecular dimensions of flexible-chain macromolecules and the double-layer thickness. The reduction of these parameters decreases the effective sample volume to a greater extent than the lower solvating power of a concentrated salt solution alone. Experiments on synthetic water-soluble polymers show that the ionic strength[65] and the type of electrolyte added to the carrier liquid may affect the relationship between sample size and retention.[69,139]

6.3 Membranes in Flow Field-flow Fractionation

A unique feature of the FlFFF system is the semipermeable membrane that is laid over the frit and serves as the accumulation wall. The possibility of wrinkling or swelling of the membrane and uncertainties in the performance of the different polymer materials used in their fabrication have been the main deterrent in the development of FlFFF. The membrane used in the FlFFF channel must meet a number of specific requirements not necessarily fulfilled by commercially available membranes. The pore size and the pore density, i.e. the number of pores per unit area, have to be uniform. Inhomogeneous pore density leads to regions of nonuniform permeability and crossflow rate. The nominal and effective pore sizes are often given by the manufacturer. While the first is an absolute measurement obtained by electron microscopy, the second must be considered an indication of the membrane performance with respect to the specific probe and to the conditions used for this determination and may not be directly transferred to samples with different physicochemical properties. For example, the Celgard isotactic polypropylene membrane is marketed with a nominal pore size of 50 nm and an effective pore size of 20 nm, but samples of much smaller diameter are retained.[65] It is known that filtration through a membrane is not a purely mechanical process and that a number of parameters contribute to the sample permeation or retention by a membrane. A higher percentage of latex particles of considerably smaller diameter than that of PS samples in tetrahydrofuran are retained by a polytetrafluoroethylene (PTFE) membrane with a nominal 20-nm pore size.[155] A regenerated cellulose membrane from Millipore with a 10 000 molecular weight cut-off (MCO) retains PEO samples in the 4000–1 000 000 molecular weight range whereas a membrane of the same material and from the same supplier with a lower cut-off shows no elution of the PEO samples.[156] Considering the lower MCO, it may be inferred that adsorption occurred in this case. Specific tests to check sample permeation through the membrane are always recommended, however. They may be carried out by connecting the crossflow outlet to a detector and monitoring the eluted carrier liquid for the presence of sample. The general scarcity of membranes capable of withstanding organic solvents has been one of the main limitations in the application of FlFFF to organosoluble polymers. Cellulose nitrate gave a good performance in the first experiments of FlFFF in ethylbenzene,[81] but many more membrane materials compatible with organic solvents such as fluoropolymers, polyvinylidene, polyaramide and PTFE are now commercially available.[155]

Ultrafiltration membranes such as those commonly used in FlFFF may be classified as cellulosic and noncellulosic. Cellulose and its derivatives were one of the first materials employed as a semipermeable membrane and successfully used in the FlFFF analysis of aqueous systems of proteins, synthetic hydrophilic polymers, and latex particles. Cellulosic ultrafiltration membranes are available in a variety of MCOs and are cast on a thicker, more permeable support material. The presence of this support adds robustness and ease of handling to the membrane. Thin-film (5–25 μm) unsupported membranes, most often noncellulosic, are more difficult to handle but their flexibility allows easy positioning on the frit wall. Unlike cellulosic ultrafiltration membranes, these mainly hydrophobic membranes do not allow wicking of carrier liquid out of the area of permeation (no leaking). An ample variety of membranes used with various solvents and samples is listed in Table 1. Besides preliminary considerations on the physicochemical properties of both the membrane material and the sample to be analyzed, an unambiguous answer on the performance of a membrane is given by a test of the absolute sample recovery.[68,137,157] This is accomplished by comparing the peak area of the output signal of a regular FFF run with the area acquired upon injecting the same sample amount through an open tube.

Table 1 Summary of membrane materials and their applications in FlFFF

Membrane material	Sample	Carrier composition
Acrylic copolymer	Proteins, lipoproteins	Aqueous solution
Cellulose	PAAm, humics	Aqueous solution
Cellulose acetate	Viruses, proteins	Aqueous solution
Cellulose nitrate	PS	Ethylbenzene
Fluoropolymer	PS	Tetrahydrofuran
Polyamide	Polyethylene, toner pigment	Xylene Toluene
Polyaramide	PS	Tetrahydrofuran
Polycarbonate	Antibodies, proteins, humic and fulvic acids	Aqueous solution
Polyelectrolyte complex	Proteins, viruses	Aqueous solution
Poly(ether sulfone)	PAAm, PEO, Poly(styrene sulfonate), PS, carbon black, Polyethylene	Aqueous solution Xylene, cyclohexane Xylene
Poly(ethylene terephthalate)	Proteins	Aqueous solution
Poly(phenylene oxide)	PS	Tetrahydrofuran
Polypropylene, isotactic	Poly(styrene sulfonate), polyvinylpyridine, proteins	Aqueous solution
Polysulfone	Minerals, cells, humic and fulvic acids, poly(styrene sulfonate), dextrans, latex	Aqueous solution
PTFE	PS, PEO, latex, silica	Tetrahydrofuran, acetonitrile
Polyvinylidene	PS	Tetrahydrofuran
Regenerated cellulose	Algae, bacteria, amphiphilic copolymers, DNA, hemoglobin, microspheres, lipoproteins, liposomes, nucleic acids, plasmids, pollens, polysaccharides, PEO, ribosomes, silicas, Poly(methyl methacrylate)	Aqueous solution Tetrahydrofuran
Regenerated cellulose, modified	PEO	Ammonium acetate in methanol solution

Literature related to the applications reported here may be found elsewhere.[137,155,157,158]

LIST OF SYMBOLS

a	axis of prolate or oblate particles
A	constant defined by DM^b
b	axis of prolate or oblate particles
b	field-flow fractionation channel breadth
b	exponent in diffusion coefficient expression
B	empirical constant in Equation (22)
c	particle or molecule concentration
c_0	particle or molecule concentration at the wall
$c(t_r)$	time-dependent sample mass concentration at elution
d	width of polymer chain
D	diffusion coefficient
D_0	diffusion coefficient at infinite dilution
D_T	thermal diffusion coefficient
f	friction coefficient
f_0	friction coefficient of an isolated sphere
F_d	diameter-based fractionating power
F_m	molecular weight-based fractionating power
H	plate height
H_i	instrumental contribution to plate height
H_l	longitudinal diffusion contribution to plate height
H_n	nonequilibrium contribution to plate height
H_p	polydispersity contribution to the plate height

H_r	relaxation contribution to plate height
J_x	flux of particles
k	Boltzmann constant
ℓ	sample mean layer thickness
l	length of polymer chain
L	channel length
$m(M)$	mass distribution as a function of molecular weight
M	molecular weight
M_0	molecular weight of repeat unit
δM	difference in molecular weight interval
M_w	weight-average molecular weight
M_N	number-average molecular weight
n	exponent in Equation (24)
N	number of repeat units
R	retention ratio in Equation (6)
R_e	equivalent sphere radius
R_g	radius of gyration
R_0	spherical particle radius
R_s	resolution
S_M	molecular weight selectivity
t^0	void time
t_r	retention time
δt_r	retention time difference
dt_r/dM	scale correction function
t_{sf}	stop-flow time
T	absolute temperature
T_c	cold wall temperature
ΔT	temperature difference across the channel
U	field-induced velocity
$\dot{V}$	volumetric flow rate
$\dot{V}_c$	volumetric cross flow rate
V^0	void volume
V_r	retention volume
$\langle v \rangle$	mean fluid velocity
v_p	zone migration velocity
w	channel thickness

Greek characters

α	thermal diffusion factor
β	exponent in thermal diffusion Equation (22)
γ	thermal expansion coefficient
η	fluid viscosity
λ	retention parameter
μ	molecular weight polydispersity
Φ	coefficient in Equation (24) or polymer volume fraction (section 4.1)

ABBREVIATIONS AND ACRONYMS

CFFF	Concentration Field-flow Fractionation
ElFFF	Electrical Field-flow Fractionation
FFF	Field-flow Fractionation
FlFFF	Flow Field-flow Fractionation
GPC	Gel Permeation Chromatography
HDC	Hydrodynamic Chromatography
HPLC	High-performance Liquid Chromatography
MALS	Multiangle Light Scattering
MCO	Molecular Weight Cut-off
MPEO	Poly(ethylene oxide) Monomethyl Ether
PAAm	Polyacrylamide
PB	Polybutadiene
PEO	Poly(ethylene oxide)
PS	Polystyrene
PTFE	Polytetrafluoroethylene
PTHF	Polytetrahydrofuran
SdFFF	Sedimentation Field-flow Fractionation
SEC	Size-exclusion Chromatography
ThFFF	Thermal Field-flow Fractionation

This chapter gives an overview of gas chromatography (with mass spectrometry) (GC/MS) of polymers and rubbers. Gas Chromatography (GC) analyzes volatile organic compounds, with an upper limit of 350 °C, which means that the compounds to be analyzed must be volatile below this temperature. The technique is able to analyze small quantities of material, which means that it is applicable for example to residual monomers, initiators, catalysts, some additives and degradation products of polymers. It is generally not suitable for analysis of organic compounds at high molecular weight or of low volatility. Care must be taken not to analyze reactive species, which may ruin columns or other parts of the equipment. Proper sample preparation is necessary before GC/MS. Sensitive and selective techniques are used to separate and extract low-molecular-weight organic compounds from polymers. The sample preparation–extraction techniques may be grouped into (1) solvent extraction from solid matrices, (2) solvent extraction of organic compounds from aqueous solutions containing polymer (e.g. biomedical implants in physiological buffers) and (3) solvent-free extraction methods. An ideal extraction method is quantitative, selective, rapid and uses little or no solvent.

Soxhlet is the old and traditional method for solvent extraction from solid sample matrices. Soxhlet is, however, time-consuming (two or three days is not uncommon), nonselective, uses large volumes of solvents and is often not quantitative. Ultrasonication and microwave-assisted extraction (MAE) are instead much more effective. Ultrasonication works by agitating the solution and producing cavitation in the liquid. The technique is useful for example to extract antioxidants from polyethylene (PE). MAE, extracts (semi)volatiles from solid matrices and has been successfully used to extract additives from polyolefins, aroma and flavor compounds from recycled polymers, and oligomers from poly(ethylene terephthalate) (PET). Solvent extractions from aqueous solutions are liquid–liquid extraction (LLE) and solid-phase extraction (SPE). LLE is rapid, but lacks in selectivity, is labor intensive and uses large volumes of organic solvents. SPE is instead suitable for separating volatile and semivolatile compounds and is a physical extraction process involving liquid and a solid phase (sorbent). Examples of separations are degradation products of PE and hydroxyacids in buffer solutions.

Solvent-free extraction methods are headspace gas chromatography (HS/GC), solid-phase microextraction (SPME) and supercritical fluid extraction (SFE). HS/GC determines volatile compounds in liquids and solids. SPME is an inexpensive, rapid and solvent-free technique with applications reported for air samples, water and soil, based on 1-cm long, thin fused silica fiber coated with a polymeric stationary phase mounted in a modified syringe.

Encyclopedia of Analytical Chemistry
R.A. Meyers (Ed.) Copyright © John Wiley & Sons Ltd

The stationary phase is available in four different kinds. SFE uses a supercritical fluid to penetrate a material. Applications are antioxidants in polyolefins, aroma vapors absorbed in PE and surface coatings and their raw materials.

This article reports applications in synthesis-related compounds in polymers, HS (headspace) analysis of polymers in indoor environments, thermal degradation products of polymers at processing temperatures, environmental degradation products, and additive systems in plastics and coatings.

1 INTRODUCTION

GC is the method of choice for the analysis of volatile organic compounds. The upper temperature limit is usually not greater than 350 °C, which means that the compounds to be analyzed must be volatile below this temperature. One of the great advantages of the gas chromatograph is its ability to detect and analyze rapidly extremely small quantities of material. Frequently the polymer chemist is concerned with trace amounts of residual monomer. If solvent processing is employed in polymer production residual solvent as well as monomer are of interest. Impurities present in the monomer may also be detectable at levels comparable with those of monomer in the finished polymer. Reliable quantitative analytical methods for these materials are necessary because they can affect such polymer properties as strength, dimensional stability, vacuum forming and molding characteristics and chemical resistance. Where polymer films are used in packaging food, residual monomer and solvent can affect the taste or odor of the food. Apart from the above-mentioned undesirable elements, certain volatile compounds must frequently be added to improve the properties of polymeric materials. They may be added at low concentrations, for example antioxidants or ultraviolet (UV) absorbers, or at high concentrations, as plasticizers or solvents for paints. For many years gas chromatographic analysis of residual monomer has also been applied to kinetic studies or in determining reaction mechanisms and reactivity ratios during copolymerization.

During the processing, lifetime and after its disposal, low-molecular-weight products are formed in the material due to degradation of the polymer matrix. The changes in the long-term properties of polymers are usually manifested as a decrease or increase in mechanical properties, weight loss, molecular weight or some other property relying on the macromolecular nature of the substrate. In addition to the changes in polymer matrix short polymer fragments and low-molecular-weight degradation products are released. Analysis of these products gives information about the degradation mechanisms and environmental impact of the material. The product analysis may also be used in lifetime predictions. Sensitive and selective techniques must be used to isolate and identify the low-molecular-weight products in polymeric materials and/or the environment where polymers are found. An appropriate extraction method combined with gas chromatographic analysis are tools for identification of wide range of low-molecular-weight products.

2 GAS CHROMATOGRAPHIC ANALYSIS OF LOW-MOLECULAR-WEIGHT COMPOUNDS IN POLYMERS

2.1 Trace Levels of Monomers, Initiators and/or Catalysts

There are in most cases many synthesis-related low-molecular-weight impurities in the polymeric materials. These include monomer rests, oligomers, cross-linking residues, initiators or catalysts, solvent rests and so on. The detection of residual volatiles can yield clues about manufacturing processes; similar materials from different manufacturers usually contain different volatiles. The solvents observed are frequently those used in polymer synthesis or processing. Other impurities can aid in the identification of specific manufacturing processes. Problems such as surface crazing, bubble formation and chemical degradation of the polymer can sometimes be caused by residues. Even if the trace amounts would not affect the performance of the end product, they may act as odorants or irritants in the material. Numerous small molecules (e.g. benzene) are also regulated because of their toxic nature.

2.2 Additives and Degradation Products of Additives

Commercial plastics and rubbers are complex materials. In addition to various polymers, commercial formulations always contain a number of compounding ingredients (additives) that are included to give particular physical and/or chemical properties. These additives include plasticizers, extender oils, carbon black, inorganic fillers, antioxidants, antiozonants, antifatigue agents, heat and light stabilizers, tackifying resins, processing aids, cross-linking agents, accelerators, retarders, adhesives, pigments, smoke and flame retardants, and others. A knowledge of additives is necessary for a number of applications, e.g. the verification of ingredients, reconstruction of recipes in unknown materials, investigation of manufacturing problems, identification of odorants or irritants that evolve from polymeric materials and so on. Because of the environmental concern about

use of chemicals, the total composition of polymeric materials, including additives has become an important issue. Many additives and their degradation products are hazardous and their migration to the surrounding environment is a point of concern. In addition to the environmental aspect, following the fate of the additives in the material gives information about the remaining lifetime of the material. The fate of the additives may be followed by quantification and identification of the products that migrate out of the material. In an opposite approach the additives remaining in the material may be measured.

Most modern polymer additives are compounds of insufficient volatility to be analyzed by GC or they are thermally unstable and decompose under the conditions of gas chromatographic separation. For additives with sufficient volatility, e.g. many alcohols, fatty acids and their esters, hydrocarbons, phthalate plasticizers and lower-molecular-weight aromatic amines and hindered phenols, GC has been set up as a standard technique of analysis.[1] The use of short columns, low-stationary phase loadings and high-temperature packing materials will extend the applicability of GC/MS to some higher-molecular-weight materials. Another approach is to convert nonvolatile components into more volatile derivatives such as trimethylsilyl ethers. However, in many cases, owing to the low volatility or thermal instability, liquid chromatography is a preferred choice for the analysis of additives.[2]

2.3 Degradation Products

The identification of degradation products is a prerequisite for the determination of degradation mechanisms of polymers. In many cases the degradation of polymers results in complex mixtures of degradation products varying in chemical composition and molecular weight, e.g. oxidation of PE may result in hundreds of different products. In contrast, polymers with weak linkages, where specific degradation, like hydrolysis occurs, generally give rise to a few well-defined degradation products. Degradation products can be formed during synthesis, processing, use and after disposal. The processing of plastics takes place at relatively high temperatures up to 300 °C. At these temperatures volatile products are formed and released from most plastics. Some of these compounds can already be dangerous to health at low concentrations. The best way to protect the employees is to identify and quantify these compounds and to make toxicological studies to obtain information about the work environment.

Environmental concerns have promoted the development of degradable plastics. To understand the environmental impact of such polymers fully, their degradation products need to be established. The nontoxicity of the degradation products is important in packaging materials, but even more important when materials are used for medical purposes. The foreign body reaction of medical implants is usually caused by leakage of degradation products or other low-molecular-weight products. The identification of degradation products in vitro is a prerequisite in determining the interaction of degradable polymers in the human body. A basic requirement for use in medical applications is the biocompatibility of both the polymer and its degradation products.

2.4 Aroma and Fragrance in Polymers

Plastic materials are particularly vulnerable to absorbing detectable amounts of contaminants because of their permeable nature. The migration of these compounds out of packaging material into the package filling must not have a detrimental effect on the quality of the filling, therefore recycled materials used for food packaging, for example, require some special consideration to ensure that nonregulated chemicals or contaminants either are not present in the material or do not migrate into food. In the case of plastic packaging waste, wasted packages might have come in contact with substances other than food, e.g. flavor components and other harmful contaminants which diffuse into the package material. There have been several studies on the aroma transport from food to polymeric packaging material.[3,4] In the life of the package, these substances may migrate from the recycled packaging material into the food. This absorption/desorption process observed in plastics makes it difficult to recycle them directly into new packaging.

In addition to typical PE degradation products, e.g. carboxylic acids, ketones, aldehydes and hydrocarbons, aroma and fragrance compounds and amines have been identified in recycled PE.[5] Some of the aroma and fragrance compounds identified are widely used in cosmetics, e.g. isopropyl myristate, isopropyl palmitate. These substances are used in products for personal hygiene, cleaning agents, food and beverages and they are probably absorbed by the packaging material during storage. Aroma and odor compounds such as limonene and 3-carene and some alcohols were detected in recycled high-density polyethylene (HDPE). Alcohols are used as basic compounds in cosmetic products and in manufacturing of household and industrial cleaning agents. In another recycling study, virgin and recycled HDPE, polypropylene (PP), polystyrene (PS) and PET were compared.[6] Generally only a few contaminants were found. Most of the contaminants were aroma compounds and were linked to foodstuffs contained in the package during the first usage.

3 SAMPLE PREPARATION–EXTRACTION TECHNIQUES

The nature of the matrix and the products to be extracted determine the choice of extraction method. Generally different extraction methods are divided into methods that use organic solvents and solvent-free extraction methods. An ideal extraction method is quantitative, selective, rapid and uses little or no solvent. Extracting products directly from the solid matrix is possible directly with an organic solvent, by Soxhlet extraction, ultrasonication or by MAE. The volatile products from the air above the polymer material may be extracted by SPME or by HS/GC. Extraction from aqueous media is best done by LLE, SPE or SPME.

3.1 Precipitation

For the extraction of additives the polymer can first be dissolved completely in a suitable solvent. After dissolution a second solvent is added to precipitate the polymer. Common organic stabilizers, plasticizers and lubricants remain in solution for analysis.[7]

3.2 Soxhlet Extraction

Soxhlet extraction is the traditional method of extracting low-molecular-weight products from solid sample matrices such as polymers[8] or soil. The sample is put in a porous holder or thimble and bathed with fresh hot solvent. The insoluble matrice remains in the thimble, while the analytes are transferred to the solvent reservoir. The extraction solvent is again vaporized, condensed and allowed to percolate through the solid sample matrice. This method is time-consuming (two or three days is not uncommon), nonselective, uses large volumes of solvent and is often not quantitative. Some analytes may be damaged by prolonged exposure to hot solvent.

3.3 Ultrasonication

Ultrasonic extraction works principally by agitating the solution and producing cavitation in the liquid. This increases the rate of transfer across the polymer/liquid boundary layer but does not increase the diffusion of compounds within the polymer. This technique has been applied to extraction of additives from polyolefins with good results,[9] e.g. a hindered amine light stabilizer (HALS) Chimassorb 944, phenolic antioxidant Irganox 1010 and phosphite antioxidant Irgafos 168 were rapidly and quantitatively extracted from low-density polyethylene (LDPE) and medium-density polyethylene (MDPE) with chloroform at 60 °C.[10]

3.4 Microwave-assisted Extraction

MAE is a relatively new method for the extraction of (semi)volatiles from solid matrices. Chemical compounds absorb microwave energy in proportion to their dielectric constants: the higher the value, the higher the level of microwave energy absorption. When using MAE a microwave-absorbing extraction solvent with high dielectric constant is used. The sample and solvent are placed in a closed chemically resistant, nonmicrowave-absorbing pressure-resistant vessel. Microwave radiation can heat the solvent to a temperature higher than its boiling point, accelerating the diffusion through the extracted matrix providing rapid extraction of analyte under moderate pressure. The extraction solvent power for the analytes of choice is an important criterion. Parameters such as heating time, and pulsed heating versus continuous heating are varied to optimize extractions. The advantages compared to Soxhlet are reduced volumes of organic solvent (10 mL versus 300 mL) and a faster extraction time ranging from 10 min to 2 h compared to 24–48 h with Soxhlet extraction. Several samples can be extracted simultaneously increasing the sample throughput. MAE has been successfully used to extract additives from polyolefins,[11] aroma and flavor from recycled polymers,[5] oligomers from PET[12] and degradation products from enhanced degradable HDPE and PP blends aged in soil.[13]

3.5 Liquid–Liquid Extraction

LLE is the traditional method for extracting organic compounds from water.[14] The low-molecular-weight compounds are transferred from one liquid phase to another immiscible or partially immiscible liquid by shaking them in a separation funnel. There are also automated methods. The analyte will go into the phase where it forms a more stable chemical species and is extracted according to its distribution constant for the particular liquid–liquid system. No universal solvent has been found, but diethyl ether, pentane, hexane, isooctane, toluene, methylcyclohexane, chloroform, and dichloromethane are some of the most usual solvents. Most organic compounds are more soluble in organic solvents than in water, exceptions being low-molecular-weight compounds with one or more polar groups, which are solvated through hydrogen bonding. LLE is still a common method, but has several drawbacks such as low selectivity, labor intensivity and the use of a large amount of organic solvent. A concentration step is usually necessary after the extraction and extremely water-soluble substances are difficult to extract. We have used LLE to extract and fractionate degradation products of casein, a biopolymer used in building materials.[15,16] Amines as well as volatile and nonvolatile organic acids were identified by a subsequent GC analysis of the

extracts. The hydrolysis products of degradable polyesters such as poly(lactic acid) and its copolymers have also been extracted from the buffer solution by LLE.[17]

3.6 Solid-phase Extraction

SPE is suitable for separation of volatile and semivolatile substances from water or organic solvent.[18,19] It can also be used to separate complex product mixtures into several fractions, to simplify the GC analysis. The principle of SPE is analogous to LLE, but it gives highly selective extractions with minimum of solvent. SPE is a physical extraction process that involves a liquid and a solid phase. The selectivity of an extraction is a function of the chemical structure of the analyte, the properties of the sorbent and the composition of the sample matrix. The solid phase should have a greater attraction for the analyte than the solvent in which the analyte is dissolved. The liquid sample is passed over a solid or ''sorbent'' that is packed in a medical-grade PP cartridge. As a result of strong attractive forces between the analytes and the sorbent, the analytes are retained on the sorbent. Later, the sorbent is washed with a small volume of a solvent that has the ability to disrupt the bonds between the analytes and the sorbent. The final result is that the analytes are concentrated in a relatively small volume of clean solvent and are ready to be injected into a GC. The sorbent normally consists of a silica substrate bonded to an organosilane compound. The specific properties of a given bonded silica sorbent are a result of the functional group covalently bonded to the silica substrate. Table 1 presents common SPE columns for different matrices and analytes.

Three types of interaction are possible between the analyte and the sorbent material, namely nonpolar, polar and ionic interactions. Nonpolar interactions are those that occur between the carbon–hydrogen bonds of the sorbent functional groups and the carbon–hydrogen bonds of the analyte. In general nonpolar extractions are less selective than polar and ion-exchange extractions. Conversely, nonpolar interactions are very effective for isolating compounds that are dissimilar in structure and is often chosen when the object is to isolate simultaneously the maximum number of analytes with different chemical properties. Most organic molecules have structures which in some part are nonpolar so this mode of interaction is often utilized. Polar interactions include hydrogen bonding, dipole/dipole, induced dipole/dipole, π-π and a variety of other interactions in which the distribution of electrons between individual atoms in the functional groups in unequal, causing positive and negative polarity. This property allows an analyte molecule bearing a polar functional group to interact with a polar group on a sorbent. Examples of possible groups are hydroxys, amines, carbonyls, aromatic rings, double bonds and groups containing heteroatoms.

Table 1 Common SPE columns for different matrices and analytes

Non-polar Extraction
Sorbents: C_{18}(octadecyl), C_8(octyl), C_2(ethyl), cyclohexyl, phenyl, cyanopropyl
Matrix: water, buffers, biological fluids
Analytes: alkanes, alkenes, aromatics, cyclic hydrocarbons, ethers
Polar Extraction
Sorbents: cyanopropyl, diol, silica, aminopropyl
Matrix: nonpolar organic solvents, oils, lipids
Analytes: amines, glycols, alcohols, aldehydes, ketones, phenols
Cation-exchange Extraction
Sorbents: propylsulfonic acid, benzenesulfonic acid, carboxylic acid
Matrix: water, acidic buffers of low ionic strength, biological fluids
Analytes: amines, pyrimidines
Anion-exchange Extraction
Sorbents: quaternary amine, aminopropyl, diethylaminopropyl, primary/secondary amine
Matrix: water, alkaline buffers of low ionic strength, biological fluids
Analytes: carboxylic acids, sulfonates, phosphates, amino acids

The third class of interaction used in sorbent extraction are ionic interactions. They occur between an analyte molecule carrying a charge opposite to that of the sorbent. Groups on analytes and sorbents can be either cationic or anionic. The retention occurs by means of an ion-exchange mechanism. Owing to the limited number of exchange sites, smaller sample volumes can be handled than when employing other interactions. The ionic charge depends on the pH of the surrounding solvent environment and it must be at a pH where both the analyte and the sorbent are charged. Furthermore the solvent should not contain high concentrations of strongly competing ionic species of the same charge as the analyte. The total ionic strength should be low. Figure 1 presents an SPE extraction scheme for aqueous matrices containing complex product mixtures, such as PE degradation products.[20,21] Figure 2 shows an SPE scheme for the extraction of polyester hydrolysis products from a buffer solution.[22]

3.7 Headspace Gas Chromatography Analysis

Headspace gas chromatography/mass spectrometry (HS/GC/MS) is an indirect method for the determination of volatile constituents in liquids and solids. Beside

Figure 1 SPE extraction scheme for aqueous matrices with complex analyte mixtures.

Figure 2 SPE scheme for the extraction of polyester hydrolysis products from buffer solution.

the analysis of volatile compounds in polymers, applications are found in analysis of sewage, water, oil, food and blood samples. The HS analysis can be divided into static and dynamic analysis. Static HS analysis indirectly determines the volatile constituents in liquid or solid samples by analyzing the vapor phase that is in thermodynamic equilibrium with the sample in a closed system.[23,24] The name static implies that there is no flow of either gas or liquid. The sample vial is first pressurized with carrier gas (helium is recommended) until its pressure is equal to the head pressure of the column. This generates a stable gas mixture. Then the carrier gas flow to the column is temporarily shut off, letting the gas flow from the sample vial to the column for a preset time.

At equilibrium the distribution of the individual compounds between the two phases will depend on their saturation pressures at the temperature of the vial and their concentration in the liquid phase. The distribution is highly sensitive to the temperature of the system. It follows that the concentration of the low-boiling sample components will be relatively much higher in the vapor phase than in the original liquid sample. HS analysis is very useful for determining volatile compounds in samples that are difficult to analyze by conventional chromatographic means, e.g. when the matrix is too complex or contains subtances that seriously interfere with the analysis or even damage the column, decomposition may occur on volatilization or dissociation products not originally present can be formed during the sampling procedure. The technique is very convenient, but has some drawbacks, e.g. solutes with very low concentrations or very low vapour pressure cannot be detected. The dynamic HS procedures involve sampling from the flowing gas above the liquid. On-column and splitless sampling are possible, thereby improving the detection limits.

The peak area for equilibrium HS/GC depends on sample volume and the partition coefficient of the compound of interest between the gas phase and matrix. This need to include the partition coefficient and thus the matrix in the calibration procedure causes serious problems with certain sample types, for which no calibration sample can be prepared. Such problems can be handled with multiple headspace extraction (MHE),[25] which is based on repeated HS analysis of the sample at equal time intervals. This procedure was originally developed for the analysis of volatiles in solid samples such as determination of monomers in polymers or for the determination of residual solvents in printed films.[26] The combination of multidimensional GC/MS with dynamic HS analysis is a powerful technique for studying the volatile organic compounds in polymers.[27]

3.8 Solid-phase Microextraction

The SPME technique was recently developed by Pawliszyn et al.[28] It is an inexpensive, rapid, solvent-free technique for isolation of organic compounds. Table 2 summarizes some of the applications where SPME has been used successfully. The applications include extraction of organic compounds from air, water and soil.[29,30] We have also demonstrated the usefulness of SPME

Table 2 Application areas for SPME

SPME applications
Industrial applications such as surfactants
Environmental analysis of e.g. water, pesticides, soil and air
Flavor analysis of food products
Toxicology analysis of blood alcohol and drugs in urine/serum
Trace impurities and degradation products in polymers

in extracting degradation products from polymers.[31,33] SPME is based typically on a 1-cm long, thin fused silica fiber coated with a polymeric stationary phase mounted in a modified syringe. For sampling, an aqueous sample containing organic analytes or a solid containing organic volatiles is placed in a vial, which is closed with a cap that contains a septum. The sheath is pushed through the septum and the fiber is immersed directly into aqueous samples or into the HS over the liquid or solid sample matrice. The analytes are absorbed on the fiber and later the adsorbed analytes are thermally desorbed in the injection port of the GC and transferred to the capillary column. Figure 3 shows the SPME extraction and injection steps. SPME is an equilibrium technique, therefore the analytes are not completely extracted from the matrix. Nevertheless, the method is useful for quantitative work and excellent precision and linearity have been demonstrated. The sensitivity and time required to reach adsorption equilibrium depend on the partition coefficients between the fiber and the analytes and the thickness of the phase. For reproducible results consistent

Figure 3 (a) SPME scheme: pass the needle with the retracted fiber through the sample vial. Depress the plunger to expose the fiber to the sample. The fiber can be immersed in the liquid sample placed in the HS above the sample. After 2–30 min of adsorption retract the fiber into the needle and remove it from the sample vial. (b) GC analysis: insert the needle into the GC injector port. Depress the plunger, exposing the fiber in the heated zone in the injector to desorb the analytes on to the column.

Table 3 Commercial SPME fiber materials

Stationary phase	Recommended use
PDMS	Volatiles, nonpolar semivolatiles
PDMS/DVB	Polar volatiles, e.g. amines, nitroaromatic compounds
PDMS/carboxen	Trace-level volatiles, gases, e.g. short olefins
CW/DVB	Polar analytes, e.g. alcohols
Polyacrylate	Polar semivolatiles, e.g. phenols
DVB/carboxen on PDMS	Flavors and odors

PDMS, polydimethylsiloxane; PDMS/DVB, polydimethylsiloxane/divinylbenzene; CW/DVB, carbowax/divinylbenzene.

timing is more important than full equilibrium. Limits of detection and quantitation are often below 1 ppb. Selectivity and sensitivity can be altered by changing the phase type.

Table 3 presents commercial SPME fiber materials. The most common polymeric coating for nonpolar analytes is PDMS; for polar semivolatile analytes, polyacrylate and CW/DVB fibers provide efficient extractions. PDMS/DVB fiber is suitable for extraction of volatile amines. The degradation products of PE were extracted with SPME fibers coated with either nonpolar PDMS or polar CW/DVB.[31,32] The film thicknesses of the fibers were 100 μm and 65 μm, respectively. The fibers were exposed to the HS over the solid polymer for 30 min at 80 °C. After the extraction the products were desorped into the injection port of the GC.

3.9 Supercritical Fluid Extraction

SFE is an extraction technique in which the extracting "liquid" is a supercritical fluid. Supercritical fluid is a compound that has been raised above its critical pressure and temperature. It has the chemical (solvent) properties of a liquid and physical (transport) properties of a gas. This means that a supercritical fluid penetrates a material as though it were a gas, but with the important difference that it has solvent properties approaching those of a liquid. It has high solvent strength, high diffusitivity, no surface tension and low viscosity. Conventional extractions use an assortment of solvents to extract different analytes. The solvent power of a supercritical fluid increases as its density increases. Thus a single supercritical fluid can extract a variety of components depending on the pressure applied. For several reasons carbon dioxide is the most often used supercritical fluid. It has a low critical temperature, is nonflammable, odorless and chemically inert, and is available in good purity at low cost. Even

nitrous oxide and hydrocarbons have been used, but they present fire, explosion or toxicity problems.

An SFE system includes a suitable pump, a heating block or oven, a pressure chamber to contain the sample for extraction, control valves and provision for collecting or trapping extracted components. The extractions can be done in dynamic, static or recirculating mode. In dynamic extraction the fluid is pumped through the sample to a receiver. The fluid passes the sample only once and evaporates leaving the concentrated analytes behind. This is an effective process when the analytes are quite soluble and the matrix is easily penetrated. In the static extraction the sample ''soaks'' in the supercritical fluid. After some time, the fluid is pumped to the receiver where the analytes are concentrated. Static extraction is used when the dissolution of analytes is slow or the matrix is dense. In recirculation the solvent is pumped through the sample repeatedly. After some time the fluid is pumped to the receiver and concentrated. The analytes may be collected into a liquid solvent and presented directly to a GC, high-performance liquid chromatography (HPLC) or supercritical fluid chromatography (SFC). The theory of SFE has been described in several books.[34] It has been used to extract organic compounds from solid materials, e.g. antioxidants in polyolefins,[35] aroma vapors absorbed in PE[36] and surface coatings and their raw materials.[37] The sample is usually a solid such as polymer, soil, sludge or food. SFE is also excellent for extraction of thermally labile and high-molecular-weight components.

4 ANALYSIS OF LOW-MOLECULAR-WEIGHT PRODUCTS IN POLYMERS

Low-molecular-weight compounds in polymeric materials are trace monomers, catalyst and solvent residues, low-molecular-weight additives and degradation products. The latter are formed in the polymer matrix during processing, use and/or after disposal. The molecular structure of the polymer and the conditions it is subjected to may result in everything from one to hundreds of different products.

4.1 Synthesis-related Trace Compounds in Polymers

There are in most cases many synthesis-related low-molecular-weight impurities in polymeric materials. These include monomer rests, oligomers, cross-linking residues, initiators or catalysts, solvent rests and so on. HS/GC/MS analysis showed the presence of residual 1,5-dioxepan-2-one monomer in poly(1,5-dioxepan-2-one).[17] Residual styrene in PS was quantified by MHE.[26] Purge-and-trap together with GC/MS has been used to analyze residual volatiles in high-temperature polymers such as polyimides.[38] The detection of residual volatiles gives clues to the manufacturing processes, e.g. poly(methyl methacrylate) samples from two different vendors yielded considerably different chromatograms.[39] Methyl methacrylate was the main component in both chromatograms, but the other volatiles varied greatly. Methyl *t*-butyl ether, saturated aliphatic hydrocarbons and phenol were identified in the sample from vendor 1, while methyl formate, acetone, methanol and aliphatic amines were identified in the sample from vendor 2.

4.2 Headspace Analysis of Polymers in Indoor Applications

The use of nonsterile casein in building materials, such as self-levelling floor-topping compound, led to various defects, including bad odor and health complaints in buildings where these materials were used. Our studies concluded that the cause of these problems is due to growth of alkali-tolerant *Clostridia* which degrades the casein. Air sampling was carried out above the casein-containing building materials by impinging in weak acidic solution and adsorption on silica gel.[13,14] The GC analysis of the HS samples showed the presence of small amounts of organic acids, amines and ammonia in the indoor air. In another study emissions from commercial floor components, such as carpet glue, poly(vinyl chloride) (PVC) carpet and plasticizers were studied by HS/GC/MS.[40]

Areas in which the use of polymeric materials are of particular interest, with respect to contamination risks, are food and pharmaceutical packaging materials. Technical polymers commonly used as such are PVC, PE and PP. Dynamic HS and GC/MS have been used to analyze contaminants in these materials.[41] Large amounts of plasticizer (bis(2-ethylhexyl)phthalate), and also glycerol, 2-ethylhexanol, butyl hydroxyanisole, and butylated hydroxytoluene were identified in the PVC samples, branched aliphatic hydrocarbons were extracted from PP/PE copolymers as well as some additives, for example 2,6-bis(1,1-dimethylethyl)-4-methylphenol. Residual vinyl chloride, butadiene, acrylonitrile, styrene and 2-ethylhexyl acrylate monomers were determined in their respective polymers by HS analysis.[42]

A glassfiber-reinforced unsaturated polyester was subjected to accelerated ageing at 40 °C or 60 °C and 80% relative humidity. GC/MS and HS/GC/MS were used to analyze the volatile products present in the material after different accelerated ageing times ranging from 0 to 6 years.[43] In most cases the same products but in varying amounts were present after different ageing times. Diallyl phthalate was the most abundant product in all the GC/MS chromatograms, but several other phthalates

were also identified. The concentration of the phthalates decreased as a function of degradation time. Several aromatic degradation products of the different phthalates, e.g. phthalic acid anhydride, benzoic acid and small traces of 2-propenyl ester of benzoic acid were also seen in the product mixture.

The volatile products lost during the extraction and concentration steps before GC/MS analysis were analyzed by HS/GC/MS. Several alcohols were identified in addition to the products already detected by GC/MS. None of the phthalates was volatile enough to be detected by the HS/GC/MS analysis. Isobutanol (2-methyl-1-propanol), allyl alcohol (2-propen-1-ol), 1-butanol and 1,2-propanediol were identified by HS/GC/MS. Temperature had a large influence on the formation of alcohols. A good correlation was found between the amounts of alcohol detected by HS/GC/MS and the corresponding phthalates detected by GC/MS. The most abundant phthalate was diallyl phthalate followed by diisobutyl phthalate and dibutyl phthalate. In the similar manner the most abundant alcohol was allyl alcohol formed by hydrolysis from diallyl phthalate. The fact that the amount of phthalates decreases during ageing, while alcohols increase also supports the idea that they are formed from the corresponding phthalates.

The HS/GC/MS analysis of nitrile rubber showed that large amounts of volatile compounds are formed and are able to diffuse out of the material even at relatively low temperatures such as 60 °C and 80 °C.[44] A large increase in the number and amount of products was seen when the temperature was raised from 60 °C to 80 °C. Trace amounts of 2-butoxyethanol and *N*-methylbenzylamine were already seen in the HS/GC/MS chromatograms before ageing. The area of the 2-butoxyethanol peak increased to 100 times the original peak after 7 days at 80 °C. After 248 days at 80 °C around 20 peaks were present in the chromatograms. Most of the volatiles formed, e.g. 2-butoxyethanol and 1-butanol, are hydrolysis or oxidation products of the phosphate additive.

4.3 Thermal Degradation Products of Polymers at Processing Temperatures

High-temperature processing of polyolefins causes thermal oxidation of the polymer. The resulting low-molecular-weight products can cause health problems to people exposed during processing. In the case of food packaging, the low-molecular-weight products can also migrate to food with potential toxicity effects. Processing conditions were stimulated in laboratory to capture and analyze the low-molecular-weight products formed in PE in the temperature range 260–290 °C[45] and in PP in the temperature range 220–280 °C.[46] Acids and aldehydes formed the majority of the 44 products in PE samples identified by GC/MS. The most toxic products (e.g. acrolein, methyl vinyl ketone and acrylic acid) were formed in relatively low quantities. In PP, 23 products, mainly aldehydes, but also ketones, acids and alcohols, were identified. In an attempt to improve the working environment for polymer manufacturing processes the evolution of gaseous degradation products of unstabilized and stabilized LDPE at 210 °C were compared.[47] In another study, 84 volatiles were identified when PE was thermally oxidized at 150–350 °C for between 5 and 15 min.[48,49] The products included aliphatic hydrocarbons, aldehydes, ketones and olefins.

4.4 Environmental Degradation Products of Polymers

With increased social awareness of the large percentage of plastics entering the waste stream, there is a renewed interest in producing plastics with enhanced degradability. Existing synthetic materials can be modified to increase the degradability or new (e.g. hydrolyzable) materials can be designed. One of the most difficult issues concerning these degradable plastics is their potential burden on the environment. A total fate analysis, including the identification of the degradation products, must be done on the newly developed degradable plastics before they are pronounced environmentally friendly or more adequately environmentally adaptable.

The environmental degradation of PE can be increased by different additives. PE is an example of a polymer with a random degradation mechanism. This means that during the degradation almost no monomer is produced. Instead a complex mixture of products varying in polarity and volatility is formed. It is necessary to characterize the low-molecular-weight products formed during the degradation. We have identified around 200 different degradation products in photooxidized or thermally aged enhanced photo- or biodegradable PE. These products included alkanes, alkenes, ketones, aldehydes, alcohols, mono- and dicarboxylic acids, lactones and ketoacids.[20,29–32,50–53] Several extraction methods for LLE, SPE, direct liquid extraction from the films, HS/GC/MS analysis and SPME were developed.

The products of the low-temperature (80 °C) thermooxidized and photooxidized PE were either extracted directly from the films by diethyl ether[52,53] or SPME was used to extract the volatilized products from the HS above the films.[31,32] SPME in comparison with the traditional HS/GC/MS method resulted in detection and identification of several times more products.[31] Despite having the same extraction temperature SPME was in particular more effective in extracting less volatile compounds. Carboxylic acids, dicarboxylic acids, ketoacids, ketones and hydrocarbons were identified in the ether extract,

while the volatile products in the HS mainly consisted of ketones, furanones and carboxylic acids. Because of the polarity of some of the degradation products the polar CW/DVB fiber was more suitable for the extraction than the nonpolar PDMS fiber.

The water-soluble products formed in PE films aged in water at 80 °C and at 95 °C were extracted from the water phase. In a preliminary study LLE was used,[54] but later an SPE method was developed, which allowed the identification of around three times as many products.[20,21] A nonselective nonpolar C_{18} column was chosen for the extraction. It is an ideal column for the extraction of a large number of products with different polarities and functional groups from water. The column was first activated with methanol (1 mL) and then conditioned with pH 2 water (1 mL). After that the pH of the sample water was adjusted to pH 2 with HCl. Sample water (1 mL) was then allowed to penetrate the solid-phase column. The column was dried slightly and the products were eluted with 1 mL hexane, 1 mL methanol or 1 mL methanol modified with 0.1% HCl. The methanol fractions were evaporated to 50 µL. The fraction with 0.1% HCl in methanol was warmed for 15 min at 60 °C to ensure methylation of the dicarboxylic acids.

The same LLE and SPE methods were used to extract products from preheated PE films aged in biotic and abiotic environments at ambient temperatures.[50,51] The SPE method using the nonpolar C_{18} columns allowed extraction and identification of dicarboxylic acids, which were not detected after the LLE. The extractions revealed the total absence of carboxylic acids in the biotic environment, while in an abiotic environment homologous series of carboxylic and dicarboxylic acids were identified. The results thus showed that the PE degradation products are assimilated by the microorganisms.

In several cases the identification of products was difficult because of the large number of peaks and severe overlapping in the chromatograms. Fractionation of the products by using polar NH_2 SPE columns allowed the identification of around 150 products in thermooxidized PE.[21] The products were eluted and analyzed in four fractions. The hexane-soluble products were dissolved in hexane and subjected to SPE. After the hexane-soluble products were removed, the remains of the products (e.g. dicarboxylic acids) were dissolved in methanolic HCl and analyzed directly by GC/MS. Methanolic HCl was used as a solvent to methylize the dicarboxylic acids, making them more suitable for the GC column. The hexane fraction was subjected to SPE. The nonpolar products (e.g. hydrocarbons) were not retained in the SPE column and they passed through with hexane. The mid-polar products (e.g. ketones, lactones and alcohols) were eluted with chloroform and the most polar fraction (e.g. aldehydes and carboxylic acids) was eluted with diethyl ether modified by 2% acetic acid. The fractionation allowed the use of different GC columns for products with different polarities which further facilitated the analysis.

Polymers that contain hydrolyzable groups as part of the main bone (e.g. aliphatic polyesters, polyanhydrides and polycarbonates) usually produce only a few different degradation products. We have used LLE to extract breakdown products from the buffer solution after hydrolysis of homo- and copolymers of lactide and 1,5-dioxepan-2-one.[17] SPE was used to extract lactic acid and glycolic acid after hydrolysis of lactide/glycolide copolymers in a buffer solution.[22] By using the SAX ion-exchange column we could demonstrate complete conversion of polylactic and glycolic acid (PLG) copolymers to lactic acid and glycolic acid. The results showed that the hydrolysis rate of glycolide units was much faster than that of lactide units giving increasing content of lactide units in the remaining copolymers. The hydrolysis of homo- and copolymers of polylactide (PLA) and polyglycolide (PGA) proceeded in three stages. During the first stage the molecular weight decreased rapidly, but no significant weight loss occurred. In stage two the molecular weight decrease levelled off and mass loss increased. At the time of total mass loss about 50% of the polymer had hydrolyzed to monomers. In stage three the hydrolysis of soluble oligomers continued until the polymers were totally hydrolyzed to monomers.

SPE with hyper cross-linked styrene-divinyl-benzene copolymer (ENV+) nonpolar columns and subsequent GC/MS analysis showed that the product patterns differ after biotic and abiotic hydrolysis of copolyesters of poly(3-hydroxybutyrate) (PHB) and poly(3-hydroxyvalerate) (PHV).[55,56] 3-Hydroxybutyric acid, 3-hydroxyvaleric acid, C_4-C_4 dimer, C_4-C_5 dimer, C_5-C_4 dimer and C_5-C_5 dimers were identified after 10 days of biotic hydrolysis. However, when biotic hydrolysis was continued 3-hydroxybutyric acid and 3-hydroxyvaleric acid disappeared and acetic, butanoic and pentanoic acids were detected instead. Crotonic acid, 2-pentenoic acid, 3-hydroxybutyric acid, 3-hydroxyvaleric acid and the four different dimers were identified after abiotic hydrolysis.

ENV+ SPE columns were also used to extract hydrolysis products of poly-L-lactide (PLLA), after aging in abiotic or biotic mineral medium for different periods of time.[57,58] After the first week acetic and propanoic acid were extracted from the biotic mineral medium; later these products were assimilated by microorganisms and were no longer detected in the biotic medium. The rate of abiotic hydrolysis was quite slow, explaining the absence of hydrolysis products in the abiotic medium. The low-molecular-weight products were also extracted directly from the films with diethyl ether. Lactide, lactic acid and lactoyl lactic acid were extracted from the abiotically aged

films. In the biotic medium lactic acid and lactoyl lactic acid were rapidly assimilated by the microorganisms, but lactide remained in the films.

4.5 Additive Systems in Plastics and Coatings

Chemical additives are frequently used to improve the useful properties and to extend the service life of polymers. Various additives are employed for these purposes, antioxidants and light stabilizers being the most important in protecting and developing desirable chemical and physical properties. The polyolefins industry consumes about half of the antioxidants and three-quarters of the light stabilizers produced for thermoplastic polymers. Besides antioxidants and light stabilizers, other additives are sometimes incorporated into the polymer matrix, e.g. PVC contains large amounts of plasticizers.

The additive packages used for polyolefins can be quite complicated, containing several antioxidants, both primary (such as hindered phenols) and secondary antioxidants, as well as antistats, slips, pigments and so on. The extraction and subsequent separation and quantitation of polymer additives in polyolefins has proven to be a challenge for the analytical chemist. There have been several workers who have investigated the separation of additives from polyolefins,[59] but extraction and recovery (at >90%) in reasonable times has been difficult. Reprecipitation (required time 0.5–2 h) or Soxhlet extraction (12–48 h) have been used for many years. Ultrasonication and MAE have been shown to be the most effective extraction methods.[10,11]

Typical polyolefin antioxidants, such as Irganox 1010, Irgafos 168 and Cyasorb UV 531 were extracted from HDPE, LDPE and PP by ultrasonication and MAE.[11] The extraction times were typically 20 min for microwave oven and 30–60 min for the ultrasonic bath with 90+% recoveries. MAE was also used in another study to extract Irganox 1010, Irgafos 168 and Chimassorb 81 from PE and PP.[60] Rapid extractions were achieved with a mixture of acetone and *n*-heptane and with chloroform alone. 91–100% of the stabilizers were extracted after only 2–6 min of microwave heating. Thick samples such as pellets had to be ground before extraction. A range of analytical techniques including GC/MS and HPLC were used to characterize the conversion products of a common polyolefin processing stabilizer, Irgafos 168, and a common polyolefin antioxidant, Irganox 1076.[61] GC/MS analysis showed that the phosphite stabilizer is oxidized to phosphate under processing conditions. Degradation products of Irganox 1076 (e.g. cinnamate) were different dimeric oxidation products and dealkylation products depending on temperature.

The primary commercial application of plasticizers is to modify stiffness characteristics of PVC resins. In general even small quantities of plasticizer have a noticeable effect. However, PVC is highly plasticized to produce soft and flexible packaging films, wire insulation, tubing, artificial leather and so on. In most flexible formulations plasticizer levels are 20–80 parts of plasticizer per 100 parts of PVC. Phthalate esters are the most commonly used class of plasticizers. Alterations in the properties of plasticized PVC are caused mainly by plasticizer lost, e.g. as a result of contact with liquid or solid media. The plasticizer loss depends on temperature, contact medium, structure and vapour pressure of the plasticizer.

Several investigations have been done on the migration of plasticizer from PVC used in food packaging or in medical articles. GC provides the most effective identification method for monomeric plasticizers in PVC.[62] An ultrasonic bath with hexane as extraction solvent was used to extract bis(2-ethylhexyl)adipate (DEHA) plasticizer from food products wrapped in PVC films.[63] The method was successfully used to study migration of DEHA to several cheeses. Migration of epoxidized soya bean oil (ESBO) plasticizer from PVC gaskets into baby food was studied by GC/MS.[64] ESBO was detected in almost all 81 studied dishes with levels ranging from 1.5 to 50.8 mg kg^{-1}. The plasticizer of 12 flexible PVC foils used as coating materials in drinking water reservoirs was investigated. The plasticizers were leached out by *n*-hexane and analyzed by GC.[65] The diffusion of dioctylphthalate plasticizer from PVC into an oil solvent, with or without stirring, was determined by GC analysis.[66] PVC used in medical and pharmaceutical packaging may contain up to 40% of additives. Both PVC bags and contamination of intravenous solutions from the PVC bags were studied by dynamic HS/GC/MS and LC.[67] Many different compound (e.g. alcohols, aldehydes, cyclohexanone, carboxylic acids, phthalates and other aromatic compounds) were present in the PVC materials. Liquid chromatographic analysis showed that some of these compounds were also dissolved in the intravenous solutions.

Volatile species produced during UV radiation of a rigid PVC construction panel were established to be a function of irradiation time.[68] Several organic and chloroorganic products were identified by GC/MS, including chloroethane, benzene, acetone, dichloropropanes, dichloromethane, chloroform, butanol, butanal, butyl formate, 1-chlorobutane and di-*n*-butyl ether. Powder coatings consist of an intimate mixture of resin, pigment and suitable additives whose function is to promote flow, adhesion or chemical curing of the finish. The growth of powder coatings business is affected by the toxicological effects of raw materials used in formulations. Different chromatographic techniques have been investigated for analyzing surface coatings and many of the raw materials and additives (e.g. plasticizers, curing agents

and surface active agents, oligomeric mixtures and so on).[69,70] Less volatile paint additives such as HALS or UV absorbers have been determined by using HS/GC.[71] GC/MS has been used to characterize the binding media in paintings.[72] Solvents in water-based coatings have been determined by sampling coating HS using SPME and GC.[73] Experimental techniques were developed to investigate the migration of UV absorbers and HALS in acrylic/melamine clearcoats during cure[74] and loss of UV absorbers in automotive coatings.[75] Automotive paint film degradation on exposure to 290–300 °C in a nonoxidizing atmosphere was characterized by thermal desorption GC/MS.[76] The volatile emissions varied depending on the paint system, manufacturer and the thermoplastic substrate.

ABBREVIATIONS AND ACRONYMS

CW/DVB	Carbowax/Divinylbenzene
DEHA	Bis(2-ethylhexyl)adipate
ENV+	Hyper Cross-linked Styrene-divinylbenzene Copolymer
ESBO	Epoxidized Soya Bean Oil
GC	Gas Chromatography
GC/MS	Gas Chromatography/Mass Spectrometry
HALS	Hindered Amine Light Stabilizer
HDPE	High-density Polyethylene
HPLC	High-performance Liquid Chromatography
HS	Headspace
HS/GC	Headspace Gas Chromatography
HS/GC/MS	Headspace Gas Chromatography/Mass Spectrometry
LDPE	Low-density Polyethylene
LLE	Liquid–Liquid Extraction
MAE	Microwave-assisted Extraction
MDPE	Medium-density Polyethylene
MHE	Multiple Headspace Extraction
PDMS	Polydimethylsiloxane
PDMS/DVB	Polydimethylsiloxane/Divinylbenzene
PE	Polyethylene
PET	Poly(ethylene terephthalate)
PGA	Polyglycolide
PHB	Poly(3-hydroxybutyrate)
PHV	Poly(3-hydroxyvalerate)
PLA	Polylactide
PLG	Polylactic and Glycolic Acid
PLLA	Poly-L-lactide
PP	Polypropylene
PS	Polystyrene
PVC	Poly(vinyl chloride)
SFC	Supercritical Fluid Chromatography
SFE	Supercritical Fluid Extraction
SPE	Solid-phase Extraction
SPME	Solid-phase Microextraction
UV	Ultraviolet

Plastics recycling recovers valuable materials to save natural resources which are limited in the long term. Reprocessing of the materials requires the identification of the various types of polymers. Difficulties in applying physical separation techniques led to the modification of methods of chemical analysis which have to be operated fast and reliably under harsh industrial environments favoring infrared (IR) methods.

In general, the plastic products to be handled can be separated into two main fractions. Domestic wastes contain only five relevant polymers in large quantities. Technical products use a broad variety of polymers containing fillers and additives, e.g. flame retardants, which also have to be identified to allow economic recycling.

Solid samples absorb IR radiation strongly, and the fundamental vibrations of the molecules are especially intense. The near-infrared (NIR) spectral range with the overtone and combination bands is appropriate for analyzing bulky materials in reflection and transmission modes. The plastics from domestic wastes can be reliably identified by the first overtone of the C−H bands between 1600 and 1800 nm. Extending this wavelength range to 1000 nm, technical non-black plastics can also be treated. In the case of black plastics, which are often used in audio and video appliances, the mid-infrared (MIR) spectral range has to be applied, owing to the reduced penetration depth of radiation into these materials. Also, larger amounts of additives such as plasticizers and flame retardants can be analyzed.

The identification of plastics from household waste requires fast scanning techniques in the millisecond range, especially if many samples are to be taken for one identification on movement. Mainly acousto-optic tunable filter (AOTF) spectrometers or grating spectrometers with diode arrays can be applied. Germanium (Ge) and indium gallium arsenide (InGaAs) detectors with extended wavelength sensitivity cover the spectral range of interest. The movement excludes Fourier transform infrared (FTIR) spectrometers with e.g. indium antimonide (InSb) and mercury cadmium telluride (HgCdTe) diodes, but its application to technical plastics is possible because these pieces are heavier and can be identified in a fixed position.

Identification for recycling means a qualitative analysis. Simple algorithms such as those forming the differences of normalized spectra are sufficient for comparing measured with stored spectra. The performance of microprocessors also allows the application of more complex algorithms such as multivariate analysis or even neural networks. The use of NIR spectroscopy in industrial recycling started with application to sorting systems for plastics from household wastes or hand-held sensors for cable recycling. The MIR technique still suffers from its sensitivity to harsh industrial environments and has been used only rarely and needs further development.

1 INTRODUCTION

Plastics are of great importance in our modern industrial world. They are used in nearly every industrial branch and can be made from cheap raw materials. A broad variety of types and blends modified by plasticizers, fillers, and pigments account for various properties required by the applications. Moreover, they have a low density (about

Encyclopedia of Analytical Chemistry
R.A. Meyers (Ed.) Copyright © John Wiley & Sons Ltd

$0.8–1.5\,g\,cm^{-3}$), can be easily processed, formed, and colored at low temperatures and can be adapted to fulfill low- and high-grade specifications of packaging materials and engineering plastics. Owing to their currently high and still strongly growing production, plastics cause environmental problems when the materials used have to be taken care of after the end of life of the product. Even after decades they do not degrade substantially in landfill sites. Therefore, plastics recycling has become a mandatory task today and will remain challenging in the future.

Recycling of plastics is carried out in different ways, as shown in Figure 1. Material recycling means that the material itself is directly reused for the manufacture of new products. Application with a high technical standard demands, of course, appropriate identification and sorting of the various types including important additives, because mixed plastics can only be processed to low-grade materials with limited use. This step is also necessary for the alternatives: raw-material recycling (feedstock), i.e. the polymer is cracked into its monomers, which are used for the production of virgin polymer granulates, and energy utilization, i.e. use of the heat of combustion. In both cases the used plastic parts have to be characterized to avoid process instabilities or ineffective processes. In the case of halogenated materials such as poly(vinyl chloride) (PVC) or brominated flame retardants, even the various thermal treatments are suspected to produce harmful constituents or to corrode the facility.

In conclusion, this means that recycling requires an effective and reliable separation system. IR spectroscopic methods have proved to be the most powerful identification techniques. They fulfill the specifications for plastics recycling within the framework consisting of

Figure 1 Recycling concepts.

government regulations, amounts and various streams of plastic waste, economic demands, and technical and industrial conditions.

1.1 Government Regulations

In the last two to three decades, the awareness of our environment has grown tremendously. Most countries are aware of the growing problem of pollution and the decrease in natural resources. The consequences force us to economize on these natural resources and to re-use post-consumer products. Meanwhile, the legislative authorities in different countries, especially in Europe, have become aware of these consequences and have taken action.

One of the most progressive countries in this context is Germany, where the Packaging Ordinance was introduced in 1991 with the goal of avoiding packaging waste. This ordinance is based on the take-back duty of packaging materials by trading companies. These companies are not in a position to take care of professional recycling, so an organization was founded which is responsible for this duty, the Duales System Deutschland (DSD). The DSD marks packaging materials with the so-called Green Dot, which demonstrates to the consumer that this material will be recycled and that the manufacturer or trader of this product has a contract with the DSD.

However, not only the packaging waste from households is covered by national legislation. In 1991, the first draft of an Electronic Scrap Ordinance was published in Germany. Since then there have been years of discussion between all stakeholders involved. The first Member States of the European Union (EU) have already issued producer responsibility legislation, and others are preparing corresponding regulations or seem to be waiting for general guidelines given by the EU. The current status of the EU Member States' legislation on take-back of waste of electrical and electronic equipment is as follows:

- (draft) legislation already developed or adopted: Austria, Denmark, Germany, The Netherlands, Sweden, Switzerland;
- draft legislation under development: Belgium, Finland, France, Italy, Norway, United Kingdom;
- no significant official steps taken: Greece, Ireland, Portugal, Spain.

Harmonization within the EU is very likely to take place at the beginning of the next millennium, as it is already standard in other sectors of waste management legislation.[1] Product return legislation has also been established in Japan, and is under construction in the USA.[2–6] The reason for this legislation all over the world is simple: consumers want to return used plastic

material and to be assured that it will be recycled in the most ecological and nonpolluting way.

1.2 Plastics Consumption and Waste

All over the world, plastics production, and hence consumption, have grown tremendously since World War II. World production of plastics in 1997 was about 150 million tons.[7] If all these plastics were to be made as one thread and passed around the earth, it would have a diameter of about 1.8 m, and if this thread were to be tied between the Earth and the Moon, it would have a diameter of about 0.5 m! This demonstrates the huge amount which is produced year by year. The world distribution can be seen in Figure 2; 28% came from North America and 32.5% from Europe. Of the 41 million tons of plastics produced in Western Europe, the largest part of about 26 million tons was the so-called standard plastics, which are polyethylene (PE), PVC, polypropylene (PP), polystyrene (PS), and poly(ethylene terephthalate) (PET) (see Figure 3). These standard plastics are mainly used in packaging, which is the largest application field of plastics today (see Figure 4). However, other branches of industry are now using more

Figure 2 World production of plastics.

Figure 3 Distribution of plastic production by plastic types.

Figure 4 Distribution of plastics according to different industries.

and more plastics for manufacturing. Some examples of the variety of applications for plastics are foils, bottles, cups, window frames, isolation mats, fenders (bumpers), synthetic fibers, housings for monitors, television (TV) sets, inline skates, biker helmets, and tools.

In summary, a huge amount of plastics is produced each year and it is expected that the production and consumption of plastics will have an annual growth of 4–5% per year. This gives rise to the question of what to do with this material after the end of life of the products made out of plastics.

There are many recycling operations all over the world and here the statistics of recycling operations in Germany will be examined.[8] In 1995, about 1 million tons of plastics were taken for this purpose; 54% came from post-consumer products and 46% were production or processing waste. This material was recycled in different ways; 38% were reused for new self-manufactured products. This means, for example, that production waste remaining from injection-molded products, which can be ground and regranulated, is reprocessed directly, because the material is well known and has properties close to those of the virgin material. Some 58% of the collected plastics was delivered to recycling companies and 4% went to waste incineration or landfill. The percentage of old plastics which was recycled to real marketable products was about 70%. This percentage is very impressive, but it has to be kept in mind that most of these products are of only low technical value, e.g. benches or sound-protection walls. The reasons for this low-level reuse will be given in the next section.

1.3 Economic and Technical Demands

Landfill or incineration is in nearly every case cheaper than recycling of mixed plastics. However, there is a

solution for an economic recycling operation which is based on the reuse of high-quality polymers for high-end applications to recover the real value of the plastic material. If the plastics have to be used at a similar grade to the end-of-life product, the various types of polymers need specifying and important additives and fillers have to be identified and sorted out of the waste stream of mixed materials. Only then is rigorous reprocessing to high-tech applications possible, because even small quantities of impurities could spoil the quality of the final product. Only sophisticated diagnostic tools can fulfill the separation requirements. They have to measure directly the chemical composition or the structure of the polymer and the other constituents. Other physical methods, e.g. based on the density, thermal conductivity, or dielectric properties, failed in the separation of polymers, especially polymers from technical applications, with sufficient purity. Therefore, various standard methods of chemical analysis have been discussed in the past whereas qualitative or semiquantitative results are sufficient. Extensive investigations were performed using X-ray fluorescence, X-ray diffraction, pyrolysis mass spectrometry, laser breakdown spectroscopy (LBDS), IR spectroscopy, etc.

The identification methods have to guarantee a high throughput to provide economic operation. The instruments have to work on-line, fast, and reliably in harsh industrial environments. They are often operated automatically or by unskilled staff and should not need much servicing. On the other hand, the instruments have to identify samples which may be lacquered, partially covered and polluted, deformed, and not precisely positioned. The recorded signals are of a quality far removed from laboratory standards. Also considering these constraints, the results obtained favor IR techniques, which are described in more detail later. However, the objects of interest, i.e. the plastic pieces to be recycled, must be examined in more detail, because the different waste streams require different IR techniques.

2 MATERIALS

The different waste streams of plastic materials have to be characterized with respect to volume, type, and identification requirements, because there are considerable differences between, e.g. packaging materials from household waste and technical plastics in audio and video appliances (e.g. portable stereos, video recorders, housings of TV sets), automotive parts [fenders (bumpers)], telecommunication equipment (e.g. telephones, mobile phones, fax machines) and data processing facilities (e.g. copying machines, computers).

2.1 Waste Streams

In general, the plastic products to be handled can be divided into two main fractions:

- the packaging materials mainly in domestic (household) waste;
- the plastics used in technical equipment.

Domestic waste contains about 5–10% plastics,[9] consisting of bottles, beakers, foil, etc. These consist predominantly of five relevant polymers, PE [high-density polyethylene (PE-HD); low-density polyethylene (PE-LD); linear low-density polyethylene (PE-LLD)], PP, PS, PET, and PVC,[9] which have only to be identified and sorted. In Germany, for example, about 535 000 t of packaging materials from household wastes were collected in 1996 and sorted by the DSD.[10] Up to now these plastics parts have been mainly sorted from the waste manually and therefore no differentiation between the different polymers is implemented. However, these plastics, apart from some special-purpose formulations, contain relatively small amounts of additives and hardly any fillers. The pieces are dyed in a broad variety of colors and can contain print and labels on the surface. Screw caps are often made of a different material from the accompanying bottle. Nevertheless, a well-processed, thoroughly graded pure recyclate can closely approach the quality of virgin materials. Owing to the low weight of the materials (60% have a weight of less than 10 g),[10] the identification has to be very fast to guarantee a relevant and economic throughput. In medium-sized recycling enterprises, the total waste throughput is in the range of about 500 kg h^{-1}, which corresponds to a throughput of about 42 000 pieces h^{-1} assuming a medium weight of 12 g. This would demand an identification rate of at least 12 parts s^{-1}. Taking into account the higher price to be obtained for sorted pure plastics, an identification rate of a few parts less per second is actually still acceptable for recyclers. However, this high identification rate means that the plastic pieces have to be identified while moving, e.g. on a conveyor belt.

Compared with the above-mentioned standard polymers, technical products use a much broader variety of plastics, e.g. acrylonitrile–butadiene–styrene (ABS), polycarbonate (PC), poly(oxymethylene) (POM), styrene–acrylonitrile copolymers (SAN), polyamide (PA), polybutadiene (PB), poly(butylene terephthalate) (PBT), polyurethane (PU), poly(methyl methacrylate) (PMMA), poly(phenylene ether) (PPE), and styrene–butadiene (SB). In the case of PA there has also to be a differentiation between the various modifications, the most important being PA6, PA66, PA11, and PA6/12 (the numbers indicate the number of different condensation units). These polymers differ in the configuration

of the two monomers involved. In addition to the pure polymers, there are also many polymer blends such as ABS/PC and SB/PPE. These blends are intended to combine the different properties of the pure polymers to give a new material with advanced properties. For these polymer blends also different amounts of ingredients have to be taken into account.

To the basic polymers there are added numerous additives and fillers. Fillers include reinforcing materials such as glass or carbon fibers to increase the stiffness of polymers. However, other fillers such as talcum, chalk, titanium dioxide (TiO_2), and calcium carbonate ($CaCO_3$), are also used to increase the volume with materials cheaper than the polymer itself. Other additives include dyes (especially carbon black in the automotive and consumer electronics industries), plasticizers, pigments, stabilizers, flame retardants (mostly based on halogens), and other additives necessary for processing or modifying material properties. The surfaces of the materials are often lacquered or treated by special techniques to create, e.g. specular effects or roughness. However, heavy metals such as lead (Pb), cadmium (Cd), chromium (Cr), and mercury (Hg) are also often found in post-consumer products.

An example of the combination of many of these components is a printed circuit board. It consists normally of glass fibers, unsaturated polyester, or phenol resins and contains polybrominated aromatic carbon hydrates as flame retardants and often heavy metals such as cadmium and antimony trioxide as synergists. In many cases the surface is lacquered and partially coated by metals. All the main constituents have to be identified to allow economic recycling.

Owing to the higher weight of technical plastics compared with packaging materials from domestic waste, the identification rate can be lower. A normal TV set has a weight of about 27 kg. The pure plastic material (without printed circuit boards) constitutes about 3 kg.[11] Assuming an average weight of only 500 g for a plastic piece, an identification rate of only 1 part s^{-1} would result in an overall throughput of 1.8 t h^{-1}. However, all important components have to be identified.

2.2 Methods of Analysis

Summarizing, the information which is necessary for recycling of plastic waste comprises:

- the main polymer and composition in the case of blends;
- main additives such as plasticizers, flame retardants, etc.;
- fillers and reinforcing fibers;
- heavy metals such as cadmium (Cd) or tin (Sn).

The most promising methods to obtain this information are spectroscopic ones because they measure directly the chemical composition or the structure of the polymer and the other constituents. From the current point of view, the most successful analytical methods are:

- NIR spectroscopy;
- MIR spectroscopy;
- laser-induced pyrolysis spectroscopy (LIPS) or LBDS;
- sliding spark spectroscopy;
- pyrolysis/mass spectrometry;
- pyrolysis/IR spectroscopy;
- X-ray fluorescence spectroscopy;
- X-ray diffraction.

NIR, MIR and pyrolysis/IR spectroscopy will be described in detail later.

Using LIPS, a high-power laser is focused onto the plastic surface under investigation and generates a plasma plume, which is observed by an ultraviolet/visible (UV/VIS) spectrometer delivering information about the vaporized and ionized atoms. Therefore, this method enables one to identify atoms, predominantly metals (especially heavy metals), chlorine and bromine as indicators for halogenated flame retardants, and silicon pointing to glass fibers as reinforcing material.

Pyrolysis/mass spectrometry uses a mass spectrometer to detect vaporized and ionized molecules and atoms which are produced by a heat source. The main disadvantage is that the material has to be transferred to a vacuum by capillary tube, which tends to become plugged by impurities.

X-ray fluorescence is mainly used for the identification of PVC plastics, because it is sensitive to heavy atoms such as chlorine and insensitive to light atoms such as carbon and hydrogen, which are the main components of polymers.

X-ray diffraction analyzes the crystal structure of materials so it is limited to polymers which crystallize in sufficient amounts.

Particularly important characteristics of the methods include:

- selectivity with respect to polymers and plastics additives;
- response rate, repeating rate of the measurement;
- penetration depth into the material to be detected;
- sensitivity to disturbances and contamination;
- user friendliness, ease of automation, and costs.

Only the IR techniques and X-ray diffraction deliver direct information on the polymer and are favored for identification. Some of the requirements of recycling cannot be fully met by these methods, e.g. the identification

of metals, heavy metals, and their compounds. Especially in the case of plastics from technical products the identification will possibly require a combination of methods of analysis. The combination of, for example, an IR technique with LIPS or LBDS could be a solution for technical plastics.

3 INFRARED BANDS OF PLASTIC MATERIALS

The main polymers, important additives such as plasticizers and flame retardants, and gaseous pyrolysis products in the gas phase are mainly composed of carbon, hydrogen, oxygen, and nitrogen. The polymers comprise aliphatic (e.g. PE) and aromatic structures and various combinations (e.g. PS). Therefore, predominant bands arise from the fundamental vibrations of the related submolecular groups and their overtones and combination bands.

3.1 Principles of Vibrational Spectroscopy

The interpretation of vibrational spectra assumes the molecules to be oscillators which are excited by absorbing IR radiation. In a classical description (Equation 1) the frequencies ν of an oscillator which consists of two atoms of masses m_1 and m_2 are derived from a force constant f and the reduced mass μ:

$$\nu = \frac{1}{2\pi}\sqrt{\frac{f}{\mu}} \qquad \mu = \frac{m_1 m_2}{m_1 + m_2} \tag{1}$$

Following a quantum mechanical description, the energy levels of the oscillator (Equation 2) are characterized by the quantum number n:

$$E_{\text{vib}} = h\nu\left(n + \tfrac{1}{2}\right) \qquad n = 0, 1, 2 \tag{2}$$

In the case of small molecules with the possibility of rotation (e.g. in the gas phase), each vibrational energy level is split up by the energy levels E_{rot} of the quantum mechanical rotator assigned to the molecule. The masses m_1 and m_2 are given by the related atoms and the force constant f by the chemical bondage between them. The simple relationships (Equations 1 and 2) explain that the combination of atoms lead to distinguishable absorption spectra of different molecules.

However, the absorption and emission of real molecules are more complicated. The complex molecules especially of long polymeric chains are assumed to build a system of coupled oscillators: The rigorous derivation of the absorption bands requires a sophisticated mathematical treatment. Various effects must be taken into account, e.g.

- the oscillators of real molecules are inharmonic, the energy levels are modified with respect to Equation (2) and allow transitions between various vibration modes;
- strongly and weakly coupled molecular groups of atoms;
- the true motion of the atoms is composed of normal modes of vibration of these groups;
- group theory determines the modes to be observed, depending on the symmetry of the groups.

The molecules absorb photons of energy ΔE_{vib} (Equation 3) from the electromagnetic field of radiation corresponding to the energy levels of the normal modes and the combinations of them, thus forming IR spectra:

$$\Delta E_{\text{vib}} = h\nu_{\text{photon}} = h\nu_i - h\nu_j \tag{3}$$

The electromagnetic fields interact directly only with polarized molecules, so causing the strong IR bands and the intensities to be proportional to the square of the derivative dipole moment with respect to the coordinate of the normal vibration mode. An effect of second order, the Raman effect (which is not discussed further here), is encountered if the radiation field interacts with the dipole moment which was transiently induced by the electromagnetic field itself. Molecules which reveal a fully symmetric distribution of the electrons such as molecular nitrogen (N_2), molecular oxygen (O_2), sodium chloride (NaCl) or potassium bromide (KBr) show no permanent dipole moment, and are inactive with respect to IR radiation.

To describe the spectra of molecules in the IR region, the vibration frequencies ν (s^{-1}) are expressed by wavenumbers $\bar{\nu}$ (cm^{-1}) and/or wavelengths λ (μm) where Equation (4) holds:

$$\bar{\nu} = \frac{\nu}{c} = \frac{1}{\lambda} \tag{4}$$

The wavelength of IR radiation ranges from 700 nm to 50 μm, corresponding to wavenumbers from 14 000 to 200 cm^{-1}. Wavelengths up to 2.5 μm are assigned to the NIR and wavelengths from 2.5 to 20 μm to the MIR region.

The IR radiation of intensity I penetrating a material of thickness Δx is diminished by ΔI by the vibrations with absorptivity α of component concentration c^* following the simple Beer–Lambert–Bouguer relationship (Equations 5 and 6):

$$\Delta I = -\alpha c^* I \Delta x \tag{5}$$

$$T = \frac{I}{I_0} = e^{-\alpha c^* d} \tag{6}$$

The transmittance T describes the response of the material with a thickness d related to the initial radiation intensity I_0. It is often expressed as a percentage, which means that T is multiplied by 100. Forming the logarithm of T, the absorbance $\alpha c^* d$ is obtained, which is linear in concentration and sample thickness (Equation 7):

$$\alpha c^* d = \ln I - \ln I_0 \tag{7}$$

A sample reflects light owing to various effects. For example, light is partially reflected at phase boundaries of different materials (e.g. air–solid sample) and from the substrate. It is scattered at inhomogeneities, impurities, and additives in the sample and gives rise to diffuse reflectance. The Kubelka–Munk theory models the diffuse reflection described in detail, e.g. by Kortüm.[12] The specular reflectance applied at small angles of incidence is obtained from the sample surface, and is governed by dispersion in the dielectric material. The evaluation of the spectra obtained has to account for the complex refractive index by applying a Kramers–Kronig transformation.

3.2 Spectra of Plastics in the Infrared and Near-infrared Wavelength Range

As mentioned above, plastic materials consist of the macromolecular polymers, fillers, plasticizers, and important additives such as flame retardants. Engineering plastics also include fiber-reinforced composites and polymeric resins and the organic constituents are predominately composed of C, H, O, and N. The constitution of the polymers comprises aliphatic [e.g. PE $(CH_2)_x$, PVC] and aromatic parts (e.g. PS) in various combinations: Structure **(1)**, PE; Structure **(2)**, PS; Structure **(3)**, PVC; Structure **(4)**, TBBA (tetrabromobisphenol A).

The interpretation of the spectra of complicated molecules is based on the concept of group frequencies. It assumes that submolecular groups of atoms are coupled weakly to other submolecular groups. The absorption bands of these groups are called characteristic bands as they always appear at the same wavelength position, only slightly modified by the weak interaction with neighboring groups. The bands characteristic of the individual molecules are called "fingerprint" bands.

(1)

(2)

(3)

(4)

The most important bands of organic compounds arise from the CH, CH_2, and CH_3 groups. These vibrations are built of the fundamental modes of motion between C and H atoms:

- stretching;
- in-plane deformation;
- out-of-plane deformation;
- wagging;
- twisting; and
- rocking.

The fundamental stretching modes of CH arise near the wavenumber 2900 cm^{-1} (wavelength 3.4 μm). The symmetric and asymmetric modes of PE lie at 2930 and 2850 cm^{-1}. The modes of CH groups neighboring C=C bonds are found at a higher wavenumber of 3100 cm^{-1} (3.2 μm), which is also valid for CH groups in aromatic rings (e.g. PS at 3000–3100 cm^{-1}). The wagging bands lie between 1180 and 1350 cm^{-1}. In chains containing CH_2 the twisting bands appear in the same wavenumber region. The rocking vibrations cause a characteristic band for long chains (e.g. PE) at 720 cm^{-1}. The spectra of a PE and a PS foil (5 μm thickness) in the MIR region are plotted in Figure 5(a) and (b) respectively.

Polymers such as PA and PU contain, in addition, NH groups. The analogous stretching modes of NH absorb near 3300 cm^{-1} (3.0 μm). OH bands are found in polymers such as cellulose acetate (CA) at 3500 cm^{-1} (2.8 μm) (see Figure 13).

In standard chemical analysis, the "fingerprint" region begins close to 5 μm and extends to longer wavelengths and shows a broad variety of bands of various origins, including especially bands with other elements such as Cl (e.g. in PVC). Important groups for identification are those of C–C, C=O, C–O–C, C–N, etc.

Gaseous species with low molecular weight show vibration band profiles broadened by rotation in low resolution. At better resolution a large number of rotational lines accompany the vibrational lines.

If the submolecular groups of polymers were to build perfect harmonic oscillators, there would occur only transitions between adjacent energy levels of the fundamental modes. Combinations of different normal modes would be forbidden. The inharmonicity of the molecular oscillators allows the appearance of overtones and combination bands. They arise when the energy of an absorbed photon is used for two or more energy quanta

Figure 5 MIR transmission spectra of (a) a PE and (b) a PS foil.

Figure 6 Transmission of an industrial PE/PP foil containing predominantly PE in the MIR/NIR spectral region, showing weak overtones and combination bands in the NIR spectrum (inset).

of the same normal mode or is split up for the excitation of two or more different normal modes. However, the absorbances of the overtones and combination vibrations are still strongly reduced compared with the fundamental vibrations. This effect is shown by the transmission spectrum of a PE/PP foil in Figure 6, where the first overtone is compared with the intensity of the fundamental mode which is in saturation.

In the NIR wavelength region, the vibrational bands are mainly generated by the overtones of stretching vibrations of groups containing hydrogen and combinations of these stretching vibrations with wagging and/or rocking vibrations. This is obvious from Equation (2), which indicates that the bands where atoms of low weight are involved appear at shorter wavelengths in the IR spectrum. A rough estimate of the wavenumber positions of the overtones and combination bands is obtained by adding the wavenumbers of the participating fundamental modes.

The first overtone of the CH stretching mode appears near 1.7 μm and the second near 1.2 μm. Comparable to the fundamental vibration, the overtones are also observed at shorter wavelengths if the CH functional group is in the neighborhood of groups such as C=C or in an aromatic C–C bond. For example, the aromatic CH band of PS or PMMA arises at 1.675 μm compared with the band of PE near 1.72 μm. Combination bands lie between the fundamental vibrations and the various overtones (e.g. 2.3 and 1.4 μm). The first overtone of NH is located near 1.5 μm and the second near 1.1 μm.

The basic concepts of vibrational spectroscopy are described here rather crudely and include only aspects to support the understanding of the classification of the plastic materials and to emphasize advantages of wavelength regions or measurement techniques to be applied. Details are described in standard textbooks of the theory of IR spectroscopy, especially of polymers [e.g. Hertzberg,[13,14] Steele,[15] Siesler and Holland-Moritz,[16] and Burns and Ciurczak[17]]. An overview on the broad variety of polymers can be obtained in collections of spectra (e.g. Aldrich Library).[18] The Sadtler Atlas[19]

and the Atlas of Buback and Vögele[20] for NIR spectra contain only a few spectra of polymers. A comprehensive collection of a variety of NIR spectra of polymers can also be found in Siesler and Holland-Moritz.[16]

3.3 The Spectra of Industrial Plastic Samples

Solid samples of organic compounds, especially their fundamental vibrations, absorb MIR radiation strongly. In addition, an increase in the thickness of the material to be penetrated by the radiation leads to an exponential decay of the transmitted intensity, as is obvious from Equations (6) and (7). Therefore, in the laboratory mainly thin films of thickness well below 100 μm or diluted samples in inactive material, e.g. KBr, are investigated to avoid saturation effects. The MIR spectral region can be applied to materials with small penetration depths of radiation. For example, fillers, pigments, and fibers can reduce the pathlength of radiation drastically by absorption, reflection, and scattering. This is especially true for carbon black, which is an important filler for black plastics, and strongly absorbs radiation of a broad wavelength range (blackbody radiation) already close to the surface.[21–23]

3.4 Near-infrared Spectra

In the NIR spectral range, the overtones and combination bands absorb orders of magnitude (10–100) less light when compared with the fundamental vibrations. Therefore, this wavelength region between 1 and 2.5 μm (wavenumber 10 000–4000 cm^{-1}) is appropriate for analyzing bulky materials in reflection and transmission when radiation penetrates a few millimeters into the material. The situation is fairly simple in the NIR region where mainly diffuse and partially regular reflection and superimposed transmission from substrates opposite to the illumination can contribute to the spectrum.

There is no need to distinguish between the different contributions to the spectra because all give rise to a transmission-like spectrum. For identification only qualitative spectra are needed. Therefore, in the figures only transmission-like spectra are plotted. Owing to the strongly varying conditions in real identification measurements the ordinate is arbitrary as no clear correlation with the illumination I_0 is possible in many cases. These properties have attracted much attention to apply NIR spectroscopy to plastic recycling.[24–55]

Qualitative reflection spectra of various plastic materials are shown in Figure 7(a) and (b), recorded with an AOTF spectrometer from engineering plastics. The polymeric samples differ in the structural composition of aliphatic and aromatic groups. The CH bands absorb in the wavelength regions 1100–1250 nm (second overtone of CH stretching mode), 1300–1450 nm (CH combination band), 1600–1800 nm (first overtone of CH stretching mode), and 2150–2500 nm (combination band). The CH bands show a significant complex shape depending on the molecular structures which allow a clear identification of, e.g. PE, PVC, PP, PS, ABS, PET, PC, PBT, and others.[16,17,19,20,24–31,34–46]

Figure 7 NIR spectra of (a) five plastic materials mainly present in household wastes and (b) five plastic materials present in electronic product wastes, recorded with a scan speed of 150 nm ms^{-1}.

There are only a few functional groups of molecules without hydrogen which show strong NIR absorption, e.g. CO. CO bands can be observed at 1900–2000 nm and are found, e.g. in the spectra of PMMA, PET and PC.[16,17,19,20,24–35]

NH groups are important in polymers such as PU and PA and the related bands appear distinctly in the spectra. The first overtone dominates near 1500 nm and overlaps the CH combination band at this position and a combination band is observed near 2050 nm.

The different polymers can be distinguished clearly, as proved by using multicomponent analysis. The plastics from domestic wastes mainly consist of various types of bottles, beakers, foils, etc. and are made of the five polymers PE, PP, PS, PET, and PVC, the last being used in decreasing amounts. Each piece is produced as a nearly homogeneous material with thickness between 100 μm and 1 mm, contains only few additives, and gives rise to spectra of good quality and high intensity in the NIR region. Dyes and prints do not substantially distort the spectra. Therefore, they differ strongly from engineering plastics. They can be reliably identified by a single band in the NIR spectrum, e.g. by the CH overtone between 1600 and 1800 nm if engineering plastic types are ignored (see Figure 8). Spectra of moving bottles or beakers measured with scan rates of 200 nm ms^{-1} are plotted in Figure 9(a) and (b). Extending the wavelength range from 1.1 to 1.8 or

Figure 8 First overtone of plastics predominantly found in household waste.

Figure 9 First overtone of CH stretching mode of bottles and beakers passing the sensor head of an AOTF spectrometer at a speed of 1 m s^{-1} (scan rate 200 nm ms^{-1}). (a) PE; (b) PVC.

even to 2.3 μm, nonblack engineering plastics containing fillers and additives (present in higher quantities) can also be identified (see Figure 7). Figure 10 shows NIR spectra in the range of 1.1–1.8 μm and demonstrates that a flame retardant TBBA could be identified in a nondyed ABS granulate. Also the plasticizer in soft PVC, which is often a phthalate, can be detected owing to its aromatic band.

The processing and the surface treatment influence the spectra to be obtained from plastic materials. Fillers also affect the spectra strongly and can absorb, reflect, and scatter NIR light. These effects result in baseline shifting and twisting. The highly transparent plastics PMMA, PC, and PE show flat baselines. PP often contains inhomogeneities which scatter the light. Fillers such as glass fibers, chalk, talcum, and pigments also scatter light. The scattering follows Mie's law, which means that it

Figure 10 NIR spectrum of ABS and the flame retardant TBBA, indicating that about 12% TBBA is present in the plastic.

increases strongly towards shorter wavelengths, which even allows an estimation of particle size. Blazing effects on the surface reflect light in special directions and can complicate light detection. These effects also result in baseline shift and twisting. Thin, transparent lacquers and prints (<10 μm) do not prevent the acquisition of useful spectra.

3.5 Mid-infrared Spectra

In the case of black plastics which are often used, for example, in audio, video, and automotive applications, the NIR spectral range is inapplicable owing to the reduced penetration depth of radiation into these materials. The MIR spectral range is appropriate for technical plastics in cases when the plastics contain high concentrations of glass fibers or fillers which reduce the transparency, especially in the case of black materials.[58–80]

The spectra are comparable to normal reflectance spectra, revealing the bands of fundamental vibrations of CH and NH stretching motion at 3.3 and 3.4 μm and the highly specific bands from the ''fingerprint'' region at wavelengths above 5 μm, including also CC, C=O, C–O–C and CX groups (X = end group) or chain segments. Many spectra of samples collected from used engineering plastics can be found in the literature.[45,58,66,67,80] Additives for processing[81] and those present in higher amounts such as plasticizers and flame retardants can also be analyzed via the MIR bands.

Carbon black is used to obtain black plastic material. In this case the penetration depth of radiation reaches only to the micrometer range. If thin foils are measured, a wave-like structure generated by internal interferences modulates the baseline of the spectrum (see, e.g. Kampffmeyer and Pfeil[82]). Spectra from reflection measurements are more complicated. Different effects can overlap and distort the spectra (see Figure 11): The reflected light can be composed of specular reflectance from the surface, diffuse reflectance from pigments and inhomogeneities from the interior, surface scattering, and even transflectance.[21–23] The band peaks of the specular reflectance spectra show a shape like a derivative spectrum, owing to refractive index dispersion. A Kramers–Kronig transformation[56,57] produces peak shapes similar to ''normal'' absorption index spectra, which can be compared with spectra obtained by well-defined sample preparation. Spectra of two important black engineering plastics are plotted in Figure 12(a) and (b), showing derivative-like peak shapes of the raw

Figure 11 Scheme of the various effects that contribute to reflection spectra.

Figure 12 MIR spectra of (a) PBT and (b) ABS as examples of industrial polymer samples.

Figure 13 MIR spectra of CA: absorption, Kramers–Kronig transformed reflection, and reflection spectra.

spectra and those obtained after Kramers–Kronig transformation. In addition, these diagrams show that defects in the spectra indicate the distorting influences described above. Figure 7(a) and (b) show the wave-like structure found in the spectra of thin foils. A comparison of the spectra of black CA from a thin foil (5 µm) and bulky material is shown in Figure 13 together with the Kramers–Kronig transformation of the latter. Many spectra obtained from important engineering plastics used in cars and audio and video products can be found in the literature.[56,64,65]

If the main polymer has to be identified and if copolymers do not have to be sorted out, the bands near 3.4 and 3.5 µm are sufficient for identification. A detailed analysis including the determination of additives such as the plasticizers, special fillers such as barium sulfate ($BaSO_4$), and polybrominated flame retardants (e.g. in PBT or ABS) requires the measurement of the "fingerprint region". Also the black plastics show more intense bands in that wavelength region. For some blends (e.g. ABS/PC and PBT/PC) and copolymers, even semiquantitative results can be derived. Materials of similar composition such as PA6, PA66, and PA12 can be distinguished.

The spectra in the MIR region are even more influenced by pollution and lacquers than those in the NIR region. The measurement of reliable spectra from the bulk polymer requires surface cleaning and treatment. It is recommended to remove the surface layer and to treat the measuring spot of the material.

3.6 Gas-phase Spectra

The treatment of materials by various heating methods, such as heating by contact with hot devices, flash heating, or shock heating, produces evolved gases. These are composed of vapors, fragments, and oxidation products of the substance under investigation. The application of controlled heating or pulse heating in air or in closed sample cells is established as a method to analyze the composition of the material and to investigate its thermal behavior.[83] In industrial environments also vapors and fragments of pyrolyzed pollutants, fillers, and additives will overlap the desired gases of the main polymers. In general, the resulting spectra should be indicative of the polymer under investigation but detailed studies on this technique are ongoing.[84,85]

Gaseous species of low molecular weight show vibration frequencies of similar groups such as condensed substances. The rotational lines lead to strong broadening

of the vibrational lines if measured at low wavelength resolution. At higher resolution a large number of rotational lines accompany each vibrational line. In air, water vapor and carbon dioxide from the environment or from partial oxidation often overlap or even dominate the spectra in the MIR region. The MIR region is useful for analyzing gas phases, because the low density or low species concentration would require very long pathlengths if the overtones or combination vibrations were applied (see the description of the principles of IR spectroscopy).

4 IDENTIFICATION MEASUREMENT SYSTEMS

The standard instruments to measure the NIR and MIR spectra of solid or gaseous samples have been widely used in laboratories for detailed chemical analysis. Applications in chemical engineering for on-line/in-line measurements for process control are increasing continuously. The original instruments were not adequate to work under the conditions of rapid qualitative analysis in an industrial environment where the identification systems have to be operated for recycling of plastics. These conditions required the development of new optics, spectrometers, photodetectors, and data evaluation algorithms or at least substantial modification of standard equipment. Appropriate components were not commercially available when the activities started at the beginning of the 1990s.

The identification of plastics from household waste requires fast scanning techniques, especially if many spectra are to be sampled for the identification of one piece while moving. Full spectra, possibly of a limited wavelength region, have to be acquired in a few milliseconds from materials of good spectral quality at a thickness of 100 μm–1 mm. These constraints favor the NIR spectral range. Although some investigations are based on Fourier transform near-infrared (FTNIR) spectrometers,[34–36] measurement during movement of the sample makes it difficult to apply. Mainly the following spectrometer types are used:

- AOTF spectrometers;[24–33,48,49]
- grating spectrometers with diode arrays;[37–46]
- reference sample absorbance at characteristic wavelengths.[53–55]

These methods allow high scan rates of sufficient spectral elements in the range of milliseconds and suitable wavelength resolution. They also fulfill the criteria of robustness in a harsh industrial environment.

The AOTF has only scarcely been used in laboratory equipment so it is described here in more detail. It uses the anisotropic Bragg effect at large angles. This effect is observed on studying birefringent crystals such as tellurium dioxide (TeO_2).[86] Ultrasonic waves generated by piezoelectric transducers form a grating of different material densities in the crystal, which diffracts incident light to an ordinary and an extraordinary beam. If the frequency of the acoustic wave is changed, the wavelength changes owing to the constant sound velocity of the crystal (650 m s^{-1}). In Figure 14 the principle of light diffraction by an AOTF crystal is plotted. The half wavelength corresponds to the lattice distance, which causes the Bragg diffraction. Oversimplified, a spectrum is scanned by an AOTF by varying the distances of the ''grooves'' and measuring the different wavelengths at a fixed angle and not rotating the grating (conventional grating spectroscopy). A detailed theoretical description of the effect was given by Yano and Watanabe[86] and Chang.[87] Based on a fast-scanning AOTF spectrometer,[88–91] the first versions of plastic identification units which met the requirements were presented at fairs (SENSORS 1988, ACHEMA 1988) and first results were published later.[24–27]

Other groups used diode-array spectrometers,[37–46] which are commercially available. The arrays comprise 128–1024 diodes which acquire simultaneously the full spectrum but the signals from the diodes are multiplexed and fed to a single amplifier. The results obtained are similar to those obtained by AOTF spectrometers.

The method to analyze the reflected or transmitted NIR radiation after further transmission through reference samples is an analogous correlation technique.[54,55] The evaluation for identification takes into account that the transmission through an inappropriate reference material reduces integrated intensity more than that through an appropriate material.

The NIR spectral range is partially covered by the following photodetectors. The uncooled germanium (Ge) photodiode is sensitive up to 1.8 μm and can measure the first CH overtone at 1.7 μm. Indium gallium arsenide (InGaAs) detectors record light up to 1.7 μm, and a

Figure 14 Principle of an AOTF.

spectrometer using it has to work with the second overtone and/or the combination band at 1.4 μm. InGaAs photodetectors are available with extended wavelength sensitivity to cover the spectral range up to 2.4 μm, but only recently, and they are expensive, which is important if arrays are applied. Cooling these types of photodetectors increases strongly the signal-to-noise ratio, often referred to as the detectivity, d^*. Other photodiodes such as lead sulfide (PbS) detectors are in principle appropriate for the NIR spectroscopy but are relatively slow.

Photodetectors for the MIR spectral region are predominantly cooled. For example, the indium arsenide (InAs) (cut-off wavelength 2.7 μm) and cooled indium antimonide (InSb) (5.5 μm) photodiodes can also be used for detection up to 2.5 μm. At higher wavelengths, mercury cadmium telluride (HgCdTe) (14 μm) is a sensitive detector which is often used. In addition, pyroelectrical sensors are applied. The cooling is performed mainly by thermoelectric effects or using Dewar vessels containing liquid nitrogen.

A typical identification unit for plastics from packaging materials in domestic waste has an enlarged measuring area and allows the simultaneous observation of reflected and transmitted light of moving samples. The light source consists of several lamps, which illuminate the measuring area ($\phi = 100$ mm) from different directions in order to increase the probability that an arbitrarily positioned moving sample reflects directly into the collecting optics, which could be, for example, a quartz condensing lens (Figure 15). In Figure 10(a) and (b) a series of spectra are plotted recorded during the fall of a PE and a PVC bottle through the sensitive area of the spectrometer. When the plastic piece enters or leaves the sensitive area

Figure 15 Scheme of an AOTF spectrometer (right) identifying falling samples (upper left) and its application for a hand-held sensor (lower left) VCO = voltage-controlled oscillator.

of the spectrometer, strong arbitrary deviations of the baseline are found. During the time interval when the plastic covers a large area of the sensitive illuminated zone of the detector head, spectra of similar quality are obtained and form a bundle of the characteristic band if plotted in one diagram. For the identification algorithm, for example, 20–50 spectra are used which allow the elimination of spectra strongly disturbed by unwanted effects.[27–32] For a moving piece the different spectra are obtained from different spots on it. This increases the probability of obtaining most of the spectra from the basic material and not arbitrarily from polluted material or inactive labels. Water droplets on the sample surface do not really distort the spectra substantially.[92]

The NIR spectral range is also useful for the identification of non-black engineering plastics.[24,26–32,48–52] In this case, FTNIR spectrometers are also applied.[40,51,52] A typical fiber-optic detector head provides a fixed measuring plane and can be moved by hand or by a robot to the sample. The light is focused on the sample (focal area $\phi = 5$ mm) by an appropriate optic, e.g. a quartz condensing lens or an out-of-plane parabolic mirror. A second optic (e.g. a quartz condensing lens, out-of-plane parabolic or elliptical mirror or Cassegrainian optic) collects the reflected light at an angle of e.g. 90° relative to the incident light and transfers it via a fiber optic to the spectrometer (Figure 15). The spectra plotted in Figure 7(a) and (b) were measured by such an identification unit.

The given examples of identification systems are not the only versions which would work. They only represent some comprehensive solutions which fulfill the following requirements:

- to account for the variable position of the sample and sample surface;
- to collect as much light in reflection or transflection of the sample as possible;
- to deal with samples which are partially contaminated or covered by labels or undefined materials.

The IR spectral range is adequate to identify engineering plastics, especially if these are black. Currently, FTIR spectrometers are used to identify plastics in the MIR spectral region.[56–78]

FTIR spectrometers analyze light by measuring the Fourier transformed intensity of a spectrum with the use of a Michelson interferometer or modified versions of it. The interferogram is obtained by a scanning mirror and the spectrum obtained by a Fourier transformation. A scheme of the basic optical configuration is shown in Figure 16. The main advantage of this technique arises from the fact that the photodetector receives light from all spectral elements simultaneously at each position of the mirror scan. In addition, the radiation

Figure 16 Operation scheme of an FTIR spectrometer based on a Michelson interferometer.

to be analyzed does not have to pass an entrance slit as in the case of a grating spectrometer. However, the Fourier transform technique is sensitive to changes in the spectrum during one scan because these changes are interpreted as a contribution to the complete wavelength range. In addition, the interferometer configuration has to be isolated against external mechanical vibrations or shocks, which is difficult to realize in an industrial environment. Performing the Fourier transformation takes time, hence FTIR spectroscopy is slow, especially if the Kramers–Kronig transformation also has to be applied. Typically up to 4 s are needed to obtain one spectrum. Its application to technical plastics is possible because these pieces are heavier and can therefore be identified in a fixed position. They allow a throughput sufficient for economical identification. However, the identification takes place at one spot on the total plastic piece. Redundant identification would require multiple time intervals.

FTIR spectrometers are suitable instruments to identify plastics in the MIR region, especially in the case of black plastics, although an AOTF spectrometer was used recently.[45] Also, if fillers and flame retardants have to be analyzed, the MIR region, where the full range or at least the ''fingerprint'' wavelength range has to be scanned, gives reliable results.

Identification using FTIR spectrometers is achieved by measuring the diffuse reflection or the specular reflection. The sensor optics are completely built by mirrors. Normally the parallel light beam which has already been transmitted by the spectrometer is focused on the sample and the reflected light is then focused on the detector. Fiber optics are difficult to apply as the fluoride fibers for the MIR region exhibit many disadvantages (brittle, low transparency, limited wavelength range, expensive) which limit their use. Hence the sensor head is normally positioned at a fixed position and provides a plane sensitive area where the sample has to be placed.

The high absorbance of condensed materials in the MIR region by the fundamental modes is of great advantage for the identification of technical engineering plastics where only small penetration depths are possible. However, surface coatings, pollutants, and moisture also absorb strongly and can prevent the acquisition of spectra from the basic material. Lacquers often have thicknesses of more than 10 μm and can complicate the extraction of the desired spectrum.[56,57] Consequently, surface cleaning and repositioning of lacquers or paints as a pretreatment is needed at the spot of identification. Techniques used are milling, brushing, etc.

FTIR spectroscopy is also applied to analyze the gases evolved from pyrolyzed plastic materials.[84,85] The plastic sample under investigation is heated by some method and the evolved gas can accumulate in a cell directly above it or be guided by a tube to an optical cell. The composition of the gas is analyzed via the transmission spectra recorded by the FTIR spectrometer. The spectra are specific for the polymers. The spectrometer configuration can be close to laboratory equipment.

Heavy metals and types of fillers and flame retardants are often difficult to identify by IR techniques. Hence it should be considered whether or not it would be a good idea to combine the IR analysis with another technique, e.g. LBDS.[31,32,39]

5 IDENTIFICATION AND PERFORMANCE

Identification for recycling means that qualitative spectra are compared with reference spectra and some algorithm decides which polymer containing which main additive is actually to be recognized. Identification by IR techniques allows a positive sorting because the algorithms search for the presence of patterns in the spectra definitely assigned to a specific material. The probability of deciding correctly can be increased by decreasing the maximum difference between the reference pattern and the test pattern, which is the defined upper limit for agreement. There arises a strong coupling of the handling techniques of the plastic pieces to be identified, allowing various rates of throughput and user-defined purity (the quality or contamination of the samples) of the recovered materials. Of course, the number of plastic types to be sorted out has to be limited to those available in the waste stream in a sufficient volume for further economic processing.

5.1 Identification Algorithms

The identification algorithms were taken from existing methods of pattern recognition, modeling, and statistical

description of data. Taking into account that only qualitative or semiquantitative information is required at a high speed, simple algorithms such as forming the differences of normalized spectra are sufficient in comparing measured spectra with stored reference spectra. The performance of microprocessors allows also the application of more complex algorithms. The simplest linear methods are described here in more detail.

It is assumed that a spectrum $y_{\text{test}}(x_i)$ is measured at n wavelength positions ($i = 1, \ldots, n$) and compared with each spectrum of a set of m reference samples $y_{\text{ref},j}(x_i)$ ($j = 1, \ldots, m$). Data pretreatment can comprise a baseline subtraction, a normalization of the spectra to 0 and 1, and a subtraction of the average of the spectrum (Equation 8):

$$\chi_j = \sum_{i=1}^{n} |y_{\text{test}}(x_i) - y_{\text{ref},j}(x_i)| \qquad j = 1, \ldots, m \tag{8}$$

Comparison of the sum of the norm of the difference spectra[94] leads to a fast algorithm which contains only additions and subtractions.[30] The decision is made on the smallest χ_j obtained for reference $y_{\text{ref},j}$ but exceeding a user-defined threshold χ_t. Taking into account the nonideal samples of used plastics, it is obvious from this procedure that small values of χ_t produce a high purity of sorted plastic materials and higher values increase the positively sorted material but with an increased number of erroneously identified pieces. The algorithm is remarkably stable and reliable also if small differences in the spectra are to be detected.

Multilinear regression can be derived by minimizing the sum of squared differences (χ^2 function) of reference and test spectra with respect to some values a_j which are obtained by differentiating χ^2 (Equations 9–12):

$$\chi^2 = \sum_{i=1}^{n} \left[y_{\text{test}}(x_i) - \sum_{j=1}^{m} a_j y_{\text{ref},j}(x_i) \right]^2 \tag{9}$$

$$0 = \frac{\partial \chi^2}{\partial a_j} = \sum_{i=1}^{n} \left[y_{\text{test}}(x_i) - \sum_{j=1}^{m} a_j y_{\text{ref},j}(x_i) \right] y_{\text{ref},k}(x_k) \qquad k = 1, \ldots, m \tag{10}$$

$$\alpha_{k,j} = \sum_{i=1}^{n} y_{\text{ref},j}(x_i) y_{\text{ref},k}(x_i);$$

$$\beta_j = \sum_{i=1}^{n} y_{\text{test},j}(x_i) y_{\text{ref},j}(x_i) \qquad k, j = 1, \ldots, m \tag{11}$$

$$a_j = \sum \alpha_{j,k}^{-1} \beta_k \qquad j = 1, \ldots, m \tag{12}$$

When testing a plastic material k, the value of a_k should be close to 1 and all others close to 0. The user can define the level near 1 which is accepted to identify positively material k and therefore define the purity of the sorted output. In comparison with Equation (8), least-squares procedures require a multiplication of two vectors and of a matrix with a vector. The inverse matrix $\alpha - 1$ can be computed from the reference spectra before the operation. If α is not singular, the m reference spectra and therefore also the corresponding plastic types can in principle be distinguished. A modified version is obtained by assuming that the tested spectrum is composed of a linear combination of the reference spectra (Equations 13 and 14):

$$y(x_i) = \sum_{j=1}^{m} a_j y_{\text{ref},j}(x_i) \qquad i = 1, \ldots, n \tag{13}$$

$$a_j = \sum_{i=1}^{n} y_{\text{test}}(x_i) \; y_{\text{ref},j}(x_i)^{-1} \qquad j = 1, \ldots, m \tag{14}$$

The plastics are distinguishable if the rank of the $n \times m$ matrix $[y_{\text{ref},j}(x_i)]^{-1}$ is m. Blends are indicated if two or more a_j are significantly different from 0. The procedures described in Equations (9–14) follow the outline of Press et al.[94] They allow one also to select the wavelength regions needed for a reliable differentiation of the reference plastics by varying them and testing the rank of the $\alpha_{k,j}$ and/or $y_{\text{ref},j}$. They were applied when testing if the above-mentioned types of plastics are distinguishable within selected wavelength regions. However, such a result does not imply that these plastics can be distinguished from all other plastic types under any conditions.

There are various methods available to model NIR and MIR data which were developed to analyze complex mixtures of chemical compounds. The linear ones are summarized by the multivariate data evaluation concepts of chemometrics where principal component analysis (PCA) and partial least squares (PLS) are powerful methods (see, e.g. Martens and Naes).[95] These methods were applied to sorting plastics in household waste and also for engineering plastics. A nonlinear generalization of these linear methods using multilayers is the neural networks,[34,35,42–46,65] which have also been tested in some cases together with fuzzy logic concepts.[44–46]

In reality, the identification has to be reduced to a limited number of plastic types because it is not possible to separate all the materials possibly present in the waste stream. Strongly contaminated, polluted, or impaired plastic pieces are better not sorted out because these parts could complicate the subsequent recycling steps. In this case, the simple methods work reliably and run fast enough for on-line identification. A problem arises when engineering plastics are sorted. They exist in many modifications which also have to be taken into account

as an extra material. The spectra are dominated not only by the composition and structure of the polymers but also by scattering, absorption, light reflection, baseline variations, and other effects. The analysis then needs the more sophisticated identification algorithms or requires extended wavelength regions for acquiring redundant information.

5.2 Applications

The interest in identification developed in parallel with the beginning of activity to recycle plastic materials. Many applications were investigated and realized on an industrial scale. Some are described here. However, some technical barriers had to be overcome before starting broad applications.

In the case of household waste plastics, mechanical separation (singulation) at adequate rates turned out to be very difficult. Actually, mainly bottles are sorted, which are heavier, and sorting about three pieces per second is state of the art. Efforts are being made to develop faster singulation, which is difficult if beakers and damaged pieces are also included. The sorting rates range up to 5–7 pieces s^{-1} and will increase further if more experience is available. The NIR technique itself is faster. As described in detail, the spectrometer can acquire spectra with sufficient quality in 1 ms and fast identification algorithms can keep up with it (the identification of 10–12 pieces s^{-1} with 50 spectra per part is no problem). In the case of bottle sorting the recovery rates are fairly high because the material is presorted. If samples of various sizes and shapes including beakers from real noncleaned waste streams are sorted, the output decreases. Labels, dyes, and inscriptions on household waste did not disturb the identification significantly. Erroneous identifications can lie below 0.1%. Heavy contamination reduces the quantity of identified samples and cleaner materials increase it. The conditions of the samples depend strongly on the presorting treatment and the collections, which vary considerably not only from country to country but also from area to area, and cannot be described adequately. The evaluation of results obtained in a single study cannot be transferred to a general situation. However, it can be estimated that output results of real applications are of the same order of magnitude of about 80–95%.

Automated dismantling, identification, and sorting have been applied to medical products, predominantly tubes and syringes. For recycling, syringes have to be washed, disinfected and dismantled into their two base parts: piston and case (tube). NIR spectroscopy identifies the polymer types before separating them; they are mainly PE, PP, and PVC.[96]

The automotive industries use various types of plastics, ranging from thermoplastic materials to composites produced by PU or reaction injection molding (RIM) technologies. FTIR spectroscopy in the MIR range has been applied to the identification of dismantled plastic pieces.[51,52,58–64,77] These are mostly covered by lacquers. The identification procedure requires pretreatment of the sample surfaces, which could take about 20 s. The identification lasts about 4 s. Studies with e.g. more than 7000 pieces revealed a purity of significantly below 1%. The weight of sorted plastic pieces is in the region of kilograms. Therefore, the time to identify the polymer is adequate as, in addition, the price of engineering plastics is higher by a factor up to five or more compared with packaging plastics. Pyrolysis/IR spectroscopy has also been applied with success.[84,85]

The electric/electronic industries produce mass consumer goods for private and industrial use which contain plastics in many variations. Plastic housings comprise the highest volume. In audio and video equipment the housings are black. In this case the application of FTIR spectroscopy in the MIR spectral region is appropriate.[58,73] The results are similar to those for plastic pieces in the automotive industry. Nonblack plastics are often used in information technologies and data processing where personal computers are produced in high volumes. MIR and NIR spectroscopy identify the polymers with sufficient accuracy and reliability. This is illustrated by an example analyzing the cases of electric homeworker tools (not dyed black) with an AOTF spectrometer for the NIR region.[27–31] The identification error was below 1% (Table 1). The NIR technique was also integrated into an automated dismantling and sorting system which treated keyboards of personal computers.

There are other ongoing investigations to treat plastic material from various industrial branches such as the building and construction industries and cable industries. The predominant aspects of identification are related to the variety of materials and their modifications used similarly as described in previous sections. Automated sorting is the objective of many investigations and progress suffers from the widely varying shapes and sizes of the products, which have to be taken into account

Table 1 Statistical test of plastic identification using an AOTF spectrometer with a hand-held sensor head in the wavelength range 1.1–1.8 μm with a 300 ms identification time and 200 scans accumulated at 300 nm ms^{-1}:[30] test results for a total of 810 homeworker tools

	Plastic type					
	PA	PP	ABS	PC	PBT	Not identified
Number of pieces	615	16	24	81	47	36
Error	4 (= PP)	0	0	1 (= PP)	0	5

to cover adequate volumes of plastics for economic operation.

6 CONCLUSIONS

In the future plastics will be used in many products in ever-increasing volumes. Their recycling saves natural resources of raw materials and areas of deposition sites, and recovers valuable substances.

NIR spectroscopy has proved to be an appropriate method to identify the plastics of packaging materials predominantly found in domestic wastes. The spectral quality of the plastics to be treated is high, allowing the analysis of fast-moving pieces at various sensing positions. The identification systems can be integrated into automated sorting lines.

The situation is more complicated in the case of engineering plastics. NIR and MIR spectroscopy can solve the problem of nonblack pieces but MIR spectroscopy requires a pretreatment in most cases. Black plastics require MIR techniques. Pyrolysis/IR spectroscopy is also applicable to engineering plastics. Integration into automated disassembly and sorting lines is currently under development and has been realized only in special cases.

LIST OF SYMBOLS

a_k	content of material k in the test sample
c^*	component concentration
c	velocity of light ($\mathrm{cm\,s^{-1}}$)
d^*	detectivity
E_{rot}	energy levels of rotations
E_{vib}	energy levels of vibrations
f	force constant
h	Planck's constant
I	radiation intensity
I_0	initial radiation intensity
m_i	mass of an atom
n	quantum number
T	transmittance
x_i	wavelength, wavenumber, or frequency
$y_{\mathrm{ref},j}(x_i)$	spectral intensity of reference sample j, measured at wavelength (wavenumber, frequency) x_i
$y_{\mathrm{test}}(x_i)$	spectral intensity of the test sample, measured at wavelength (wavenumber, frequency) x_i
ΔI	difference in intensities
Δx, d	thickness of material
α	absorptivity
$\alpha_{k,j}$	matrix built from the spectra of the reference samples
$\beta_{k,j}$	matrix built from the spectra of the reference and test samples
χ^2	sum of squared differences
χ_j	sum of normalized differences
χ_t	threshold value
λ	wavelength (μm)
μ	reduced mass
ν	frequency of molecular vibration or photons ($\mathrm{s^{-1}}$)
$\bar{\nu}$	wavenumber ($\mathrm{cm^{-1}}$)

ABBREVIATIONS AND ACRONYMS

This article provides a comprehensive review of the application of infrared (IR) spectroscopy in the analysis of polymer crystallinity. A brief description of the theory behind the analysis of orientation in polymers using IR spectroscopy is followed by a comparison of various sampling methods for Fourier transform infrared (FTIR) spectroscopy. These include transmission, attenuated total reflectance (ATR), external reflection, diffuse reflectance, photoacoustic and emission spectroscopic techniques. Various modes of measurement, such as polarized IR measurements, deuteration and rheo-optical measurements to obtain more information from IR spectra and make the interpretation of spectra easier, are also discussed. The use of IR spectroscopy in analyzing both semicrystalline polymers and liquid crystalline polymers is presented. In the case of semicrystalline polymers, applications involve measuring phase transformations, chain conformation/packing, degree of crystallinity, crystallization kinetics, isomer ratios and chain alignment during mechanical treatment. In the case of liquid crystalline polymers, IR spectroscopy has been used to analyze molecular orientation, segmental mobility, photo-induced reorientation and phase characterization/transformations. A comparison of IR measurements with other techniques used to analyze crystallinity in polymers such as X-ray diffraction (XRD), differential scanning calorimetry (DSC), nuclear magnetic resonance (NMR) spectroscopy, Raman spectroscopy and neutron scattering has been presented.

1 INTRODUCTION

Semicrystalline polymers exhibit short-range as well as long-range ordering of macromolecular chains. Both types of ordering contribute towards the degree of crystallinity of the polymer. Liquid crystals (LCs) are substances that exhibit long-range order in one or two dimensions, but not all three.[1,2] LCs and liquid-crystalline polymers (LCPs) have gained scientific and technological importance because of their use as display materials, materials for optical information storage, high-modulus fibers, and high-temperature plastics. An understanding of the order and structure in both LC and semicrystalline polymer systems, using techniques such as IR spectroscopy, is essential for designing these materials for various applications and predicting their properties. Research on such polymers includes studies of phase characterization/transformations, orientation under the influence of external fields, photo-induced reorientation, dynamics, and segmental mobility.[3]

IR spectroscopy is one of the most commonly used spectroscopic tools because the method is rapid and sensitive with sampling techniques that are easy to use. IR spectroscopy measures the vibrational energy levels of molecules. The characteristic band parameters measured in IR spectroscopy are frequency (energy), intensity (polar character), band shape (environment of bonds), and the polarization of various modes.[4] A very good review of the theory and applications of IR spectroscopy for investigating polymeric systems is provided in the books by Koenig.[4,5]

When a polymer passes from the amorphous to the crystalline phase, either new absorption bands appear in the IR spectrum, or splitting occurs in the bands present in the spectrum of the amorphous material.[6] With certain polymers, several bands have been found to increase in intensity as the polymer passes from a crystalline to an amorphous phase. The former bands are termed ''crystalline bands'' and the latter are called ''amorphous bands''. Since the symmetry of a molecule in a crystal field is usually lower than the symmetry of a free molecule, certain types of vibrations, which are inactive in an amorphous polymer, may be active in the unit cell of a three-dimensional or one-dimensional crystal. Crystalline bands may also appear, caused by the change in the

Encyclopedia of Analytical Chemistry

configuration of the chain in the crystal cell of the polymer compared with its configuration in the amorphous state. The vibration of an individual molecule in a crystal field, combined with the interactions of vibrations between chains in the crystal cell, presents a complete picture of the process. Intermolecular interactions such as those that occur in the crystalline state will influence the detailed structure of the absorption band associated with a given mode, as well as its intensity,[7] but are not likely to greatly affect the frequencies of group normal vibrations. A special case of an intermolecular interaction with a large influence on group frequency is hydrogen bonding.

This article discusses some background theory on the use of IR to investigate crystallinity of polymers, describes some of the experimental methods and sampling techniques commonly used, and outlines applications related to structure elucidation of semicrystalline and liquid crystalline polymers that IR spectroscopy has been used for. The article concludes with a comparison of IR versus other commonly used techniques for characterizing such polymers.

2 ANALYSIS OF ORIENTATION IN POLYMERS USING INFRARED SPECTROSCOPY

The fundamental modes of the single chain are split into various spectral components in the crystal if the intermolecular forces between polymer chains are sufficient. Physically, such splitting, called the correlation field splitting or factor group splitting, occurs as a result of the resonance interactions of analogous vibrations undergone by individual chains in the unit cell. The number of theoretically expected bands depends on the number of molecules in the unit cell.[4] For an infinite, ordered polymer, symmetry reduces the vibrational analysis to the analysis of the translational repeat unit. This is generally not a bad assumption for high-molecular-weight polymers, but there are usually some secondary IR bands that cannot be assigned to fundamentals, combinations or end-groups because of the semicrystalline nature of even the most highly regular polymer.

Vibrational spectroscopy can be used to study conformational defects and to distinguish between stereoisomers. Mass configuration plays a dominant role in rotational isomerism. Crystallization usually results in stabilization of the lowest energy isomer, whereas all forms are present in the liquid state. Since the amorphous state in polymers is essentially a disordered state comparable to liquids, the spectrum of a partially crystalline polymer in which rotational isomerism can occur is essentially a superposition of the spectra of various isomers. Also, because rotational isomers have different symmetry, the number of modes associated with a given group can be different for different isomers. In certain cases, amorphous absorption bands are formed on passing from the crystalline to the amorphous phase, which may be due to the breakdown of selection rules operating in the crystal or to the existence of rotational isomers which are absent in the crystalline phase.[6] The intensity of amorphous bands is usually low.

Polyethylene, having closer chains than any other polymer, exhibits the largest crystal field splitting.[4] One of the limitations of IR spectra for determination of polymer crystallinity is that very few polymers exhibit the crystal field splittings observed in specific cases, such as polyethylene, since the splitting is very sensitive to the separation of the polymer chains. However, even if most polymers do not exhibit crystal field splittings due to intermolecular or crystalline packing, band pairs can arise from intramolecular helical splitting, such as in the case of polypropylene. Polymers can exhibit resonance splitting of bands associated with interaction between analogous groups along the polymer chain. Polymers having a helical chain structure, for example, show splitting of certain vibrations into components parallel to the axis of the helix and perpendicular to the plane of the helix. Most IR correlations of spectral features with crystallinity or density are based on the amount of rotational isomer preferred in the crystalline state, which, on average, may correlate with crystallinity or density. Empirical correlations of IR bands to the vibrations of partially ordered polymers have been reported for a number of polymers.

The sensitivity of IR spectroscopy has been improved tremendously by the use of multiplex optical devices, such as the Michelson interferometer, which allow continuous, simultaneous detection of all transmitted energy. This has led to the development of FTIR spectroscopy.

2.1 Sampling Methods for Fourier Transform Infrared Spectroscopy

IR spectra depend on sample preparation techniques, and, depending on the specimen to be investigated, various sampling techniques can be used. Transmission spectroscopy is the most commonly used technique, has the highest signal-to-noise ratio, and is the easiest to quantify. For transmission IR spectroscopy, the primary dimensional requirement on the polymer sample is that it be sufficiently thin. Various techniques are used to produce thin films, including solvent casting, melt casting, and microtoming. Orientation in polymer specimens can be achieved in several ways, including stretching the film or fiber after heating or swelling if it is necessary. Stretching and rolling produce different kinds of chain

orientation in a polymer film. In a stretched specimen, a particular crystallographic axis will become aligned along the stretch direction, but all orientations of the crystallites about this axis will be equally probable.[7] In rolled specimens, double orientation is produced due to the axis aligning with the rolling direction and the crystallographic planes orienting parallel to the plane of the film.

Another mode of operation that can be used to obtain spectra, especially when it is difficult to obtain very thin films or if the polymer samples have a low transmission, is the ATR mode. This is a contact sampling technique that involves a crystal such as germanium with a high refractive index and low IR absorption in the IR region of interest. The ATR mode is more general than the transmission mode and also applies to samples irrespective of their thickness or their absorbance.[8] The ATR technique also has some disadvantages in that it shows a great deal of uncertainty depending on contact between the sample and the high-index crystal.[9] ATR has been very useful in the studies of aqueous systems because it is possible to subtract the water absorption in a reproducible fashion. In transmission spectroscopy, a comparison of two bands of a spectrum poses no problems because the analyzed thickness is the sample thickness itself. However, in ATR/FTIR such a comparison is not possible because the analyzed thickness now depends on the wavelength. Therefore, two distinct absorption bands corresponding to remote spectral zones can be compared in transmission but not in ATR spectroscopy. The transmission method helps analyze the core of the sample, while ATR analyzes the surface. Therefore the methods are complementary.

The external reflection technique, involving a sample deposited on the surface of a smooth mirror-like surface, is very useful in the analysis of coatings and adhesives on the surface of metals. The polarization sensitivity of this technique adds to its usefulness. However, the major difficulties with this technique are the appearance of asymmetric absorption modes and the shifting of some of the mode frequencies.

Sample preparation is often the most time-consuming part of the IR analysis. Diffuse reflectance spectroscopy has been proposed as a ''no preparation IR technique''. However, it works well only on highly scattering and weakly absorbing samples.[4] In addition, symmetrically shaped absorption bands are represented as asymmetric ''differential-like'' band shapes. The use of IR absorption spectra to investigate the conformation of polymers in solution is difficult because most solvents themselves absorb in the range investigated, and it is difficult to choose compensating conditions for solvents such as dichloroacetic and trifluoroacetic acids.[6]

Photoacoustic spectroscopy is based on the principle that modulated IR radiation striking the surface of a sample will cause the surface to alternately heat and cool with IR absorption.[4,9] This technique requires minimal sample preparation and provides the capability of studying opaque samples and depth profiling the sample. However, it has a low signal-to-noise ratio and high absorption related to photoacoustic saturation.

Emission spectroscopy can be used on samples that are opaque and cannot be studied by transmission spectroscopy. But high temperatures are usually required and sample decomposition could be a problem, especially in the case of polymers. IR microspectroscopy involves using IR microscopes for both transmission and reflection measurements and can have a spatial resolution of about 50 μm. It is developing into a valuable tool for polymeric samples, especially because it is relatively easy to obtain a minute polymer sample.[4]

2.2 Modes of Measurement

Vibrational spectroscopy is very sensitive to the degree of order present in a polymer sample, but the interpretation of results is not always straightforward. A particular sample can be envisaged to be a mixture of several phases: ordered conformations, regular or irregular chain folds, and a bulk amorphous phase. Experimentally, the major problem arises from the fact that it is often difficult to separate the contributions of the various phases.[4,7] The amorphous component also contributes to the spectrum of a semicrystalline material. Therefore, by subtracting the spectrum of an amorphous component, appropriately scaled, from that of a semicrystalline material, a difference spectrum is obtained, which is usually characteristic of the crystalline phase. Also, various modes of measurement, such as the ones listed here, can be used to get information that can make the interpretation of spectra easier and provide more information about structure and order in the specimen.

2.2.1 Polarization

The intensity of an absorption band is proportional to the square of the scalar product of the transition moment and electric field vectors. As a result, if the electric field vector is perpendicular to the transition moment vector, no absorption will occur. This fundamental relationship is the basis for utilization of polarized radiation to study spectra of oriented polymers. The study of oriented polymers with polarized IR radiation allows, with certain restrictions, the determination of orientation (with respect to the molecular structure) of the transition moment for a given normal mode. This makes it possible to classify bands in the spectrum and establish their origin.[7]

Polarized IR measurements permit determination of the direction that the transition moment associated with

a given band makes with the fiber axis, which is often significant in establishing structural parameters. The dichroic ratio of the corresponding absorption band is the experimental quantity related to the orientation of the transition moment for a given mode. When a specimen is stretched, the chains do not all become oriented in the same direction, but assume a distribution of orientations about this direction. In general, it is not possible to obtain the form of this distribution based on dichroic ratio measurements. However, some general conclusions about the nature of the distribution can be obtained by tilting an oriented specimen at various angles to the polarized beam. Individual spectra of polychloroprene were obtained using light alternately polarized parallel and perpendicular to the direction of elongation, and the dichroic ratio was evaluated.[10] In cases where the polymer chain exhibits symmetry, a qualitative knowledge of an absorption band helps associate the band with certain of the symmetry species, and thereby with certain normal modes of the molecule. A number of studies have been conducted to obtain IR spectra and measure dichroic ratios using polarized radiation[8,10–17] and to compare the results with the spectra obtained using unpolarized radiation.[18]

With respect to the sample, several problems could arise.[7] First, reflection at the surface and scattering in the interior will modify the incident intensity value from that observed in the absence of a sample. These losses can be corrected by subtracting the optical density in a nearby region that is free of absorption bands from the peak optical density. Secondly, for birefringent specimens, the propagation of a beam of plane polarized radiation can be different in the interior of the specimen and in air. Because of the symmetry of oriented polymer specimens, although the maximum absorption occurs when the electric vector is parallel to the transition moment, for the gross specimen the maximum absorption occurs with the electric vector along or perpendicular to the fiber axis. Thirdly, the specimen may exhibit form dichroism, which might have to be subtracted from the observed dichroism to obtain the structural dichroism.

2.2.2 Deuteration

The use of partially deuterated chains in the analysis of the conformational structure of polyethylene was investigated[5] because of the problems associated with identifying and assigning bands to localized vibrations. This problem is especially significant when there is an overlap of such bands in a specific spectral region, and the vibrations are not entirely localized. When an isotopic substitution is made in a molecule, the forces between the atoms remain unchanged, and only the masses of the hydrogen atoms change in magnitude. The result is that the normal modes, which involve primarily the motion of hydrogen atoms, will be lowered in frequency upon deuterium substitution.[7] Moreover, if a molecule contains different kinds of hydrogen atoms it is possible to deuterate these selectively, enabling a more detailed identification. Finally, in cases where there is interaction between hydrogen modes and other modes, such interaction will usually disappear upon deuterium substitution, indicating its presence in the original molecule.

A method of detecting the presence of inter-chain interactions is to study the spectra of mixtures of deuterated and normal polymers. When a neighboring chain has different frequencies for comparable normal modes, any band splitting due to inter-chain interactions will disappear because the interaction between different frequencies is much smaller. This change in band contour qualitatively identifies the existence of an interaction.[7] IR spectra have been obtained using deuterated samples for a number of polymers, especially for polyethylene.[19,20]

2.2.3 Rheo-optical Measurements

Rheo-optical FTIR spectroscopy is based on the simultaneous acquisition of stress–strain data and FTIR spectra and is used for characterization of transient structural changes during deformation and stress-relaxation of polymers.[11] This technique has been extensively used for studying phenomena such as strain-induced crystallization in polymers.[10–12,22–24]

2.3 Semicrystalline Polymers

FTIR spectra of various polymers have been obtained to elucidate the order present in the specimen. IR spectra can be used for measurements of stereoregularity, conformation, characterization of polymer blends, deformation in polymer systems, dichroic measurements of orientation, trichroic measurements of orientation (for samples which have orientation with a three-dimensional character), measurements of intermolecular and intramolecular interactions and morphological units and structural changes as a result of thermal annealing or mechanical orientation.[4]

The most common applications have involved studying phase transformations in semicrystalline polymers. IR spectroscopy has been used to measure orientation in the crystalline and noncrystalline phases using polarized radiation[25] to follow changes from one crystal form to another and changes in degree of crystallinity (Figure 1) when the specimen is subjected to thermal annealing.[26–31] The intensity of selected peaks is directly proportional to the degree of crystallinity of

Figure 1 Far-IR spectra of differently ordered polyurethane samples measured at room temperature[13] (annealed at the indicated temperature (°C) for 2 h). [Reprinted with permission from D.Y. Shen, S.K. Pollack, S.L. Hsu, *Macromolecules*, **22**, 2564–2569 (1989). Copyright 1989 American Chemical Society.]

the polymer. IR spectroscopy can also provide valuable information about chain conformation/packing using hydrogen bond vibrational modes and can elucidate microphase separation between hard and soft segments in polyurethanes.[13] It has been used to measure the degree of crystallinity of semicrystalline polymers[11,32–37] as well as the temperature coefficient of crystallinity.[38] Crystallization kinetics during thermal annealing can also be followed using this technique, and Avrami coefficients have been estimated based on IR spectra.[39–41] IR spectra can be used to distinguish between intermolecular and intramolecular effects[42,43] and elucidate chain conformations[20] in the polymers. Phase separations in blends of polymers[44] and photoinduced orientation of groups[15] have also been interpreted from IR spectra. The conformation of poly(ethylene oxide) chains in a unit cell has been elucidated using IR.[14]

Another area where IR spectra can provide valuable information is in distinguishing between various isomers in the same polymer. Crystal structures of two samples with different fractions of *cis*- and *trans*-components have been compared.[45,46] Similarly, IR spectra have been used to compare samples with different tacticities,[47] such as atactic and isotactic polystyrene (Figure 2), where the tacticity strongly influences the crystallizability.[48] Evolution of crystalline *trans* and gauche conformations during thermal treatment has also been investigated.[9,49] Orthorhombic to hexagonal phase transitions in ultra-drawn polyethylene have been elucidated using IR.[18] IR spectra can help determine the extent of isotopic fractionation in deuterated samples.[19]

Rheo-optical spectroscopy helps measure chain alignment during mechanical treatment.[10–12,22,23] Most

Figure 2 Comparison of IR spectra of atactic polystyrene dried gel, isotactic polystyrene gel dried from various polymer concentrations and solution-cast isotactic polystyrene film.[48] [Reprinted from X.M. semicrystalline polymers undergo uniaxial stretching at small deformations, and exhibit an increase in the degree of orientation or crystallinity with time. The strain-induced crystalline-sensitive absorption bands were found to be accentuated when the sample was subjected to strain-induced crystallization. Crystal phase transformations under elongation (Figure 3) have been followed in situ using IR spectroscopy.[11]

Finally, the distribution of additives in different phases of a semicrystalline polymer has also been studied using IR spectroscopy.[50] It can also provide valuable information about crystal structure changes induced by doping a given polymer with a compound such as iodine.[16,51] Therefore, valuable information about the conformation structure of semicrystalline polymers can be obtained from IR spectra. Table 1 provides a list of IR spectroscopy studies involving some common semicrystalline polymers.

2.4 Liquid-crystalline Polymers

IR spectroscopy has been widely used to study interactions between chains and conformational order in

Figure 3 FTIR polarization spectra taken during elongation at 348 K of a poly(vinylidene fluoride) film showing a decrease in its initial II(α) crystal structure as it transforms into the all-*trans* I(β) form during elongation.[11] [Reprinted by permission from H.W. Siesler, *J. Polym. Sci. Polym. Phys. Ed.*, **23**, 2413–2422 (1985). Copyright © 1985 John Wiley & Sons Inc.]

polymers.[4] The molecular interactions are a function of the nature of the phase, which in turn determines the relative arrangement of functional groups. Hence, IR can be used to study the dependence of the mesophase microstructure (in LCs and LCPs) on molecular interactions. Specifically, analysis of absorption bands can provide information about the degree of order/disorder, molecular orientations under the influence of external fields, etc. Modern rapid-scan FTIR spectrometers can follow the kinetics of molecular motion with a time resolution of the order of nanoseconds per spectrum. The inherent limitation is the ability to record spectra of periodic events. Orientation relaxation and segmental mobility within LCs and LCPs are good examples of reproducible phenomena, and time-resolved FTIR can be used to investigate these phenomena at a molecular level. Examples of various molecular phenomena in LCs and LCPs investigated using IR spectroscopy are presented.

2.4.1 Molecular Orientation

Shibaev et al.[55,56] have shown that polarized IR spectroscopy can be used to study orientation in a mechanical field of LC polyacrylates and polymethacrylates involving cyanobiphenyl mesogenic groups in the side chains. The length of the mesogenic group was varied by varying the length of the methylene sequence within the side chain. Their results established that the type of orientation depends on the molecular weight of the polymer. The axes of the mesogenic groups were oriented along the shear direction for low-molecular-weight polymers whose degree of polymerization (DP) was <100, while they were normal to the shear direction when DP was >100. By estimating the degree of orientation as a function of temperature, Shibaev et al. were able to show that the content of gauche isomers in the different mesophases was different, thereby leading to different degrees of orientation.

Another example of mechanically induced orientation in side-chain LCPs is shown in the work of Zhao and Lei,[57] in which a thin LCP film was cast on the surface of a supporting polyvinyl alcohol film, which could be prepared and stretched over a wide temperature range. They obtained an order parameter of *ca.* 0.4 by IR dichroism measurements for the mesogenic groups at a draw ratio of 1.5, i.e. at a deformation of only 50%, indicating rapid macroscopic alignment of the nematic domains along the

direction of the applied mechanical field (Figure 4). They also quantified the effect of the flexible spacer (methylene sequence) group and demonstrated that a shorter spacer group provides a stronger coupling between the mesogenic groups and the backbone chain. This leads to favorable interaction between the nematic domains and the applied mechanical field.

Segmented block copolymers with alternating liquid crystalline hard and amorphous soft segments are a new class of thermoplastic elastomers.[58] The hard LC domains behave like physical cross-links and become macroscopically anisotropic during shear. Thus, highly oriented thermoplastic materials can be obtained. MacKnight et al.[59] investigated the effect of strain on orientation in liquid crystalline polyurethanes, which have applications as high-strength fibers. It was shown that mechanical strain orients the nematic mesophase in the direction of stretching. The N–H stretching vibrations in the high-temperature IR spectra (Figure 5) point towards microstructural changes during thermal transitions.

Similar molecular orientation studies have been performed[60] with photochromic Langmuir–Blodgett films, which show promising applications in the area of optical information storage media. The system under consideration was a polyion complex with azobenzene-containing fatty acid and polycation with LCs mixed with stearic acid-d_{35}. Studies were performed using FTIR transmission and reflection–absorption spectroscopy. The results revealed that the orientation of molecules in LCs is controlled by the *trans–cis* photoisomerization of the polyion complex at elevated temperatures, but the orientation is unaffected at room temperature. The state of the LC is different at these temperatures and this explains the difference in orientation.

Some LCPs exhibit a unique molecular structure at the surface, and this structure is completely different from that in the bulk. ATR/FTIR spectroscopy using polarized radiation has been used to characterize molecular orientation at the surface of stretched polymer sheets.[61–65] In addition, polarized specular reflection FTIR spectroscopy has been used[66,67] to characterize the surface orientation of extrusion-molded thermotropic LCPs. The reflection IR method is reliable for the analysis of the surface structure, but caution must be exercised for intense absorption bands because of the effects of the refractive index dispersion on the ATR spectra. The effect of the draw ratio, the flow characteristics, and the morphological structure on the orientational distributions at the surface of the LCPs has been studied.[67]

2.4.2 Segmental Mobility

The study of segmental mobility as a function of external (electric or electromagnetic) perturbation is fundamental in order to understand the dynamics of such molecular processes within LCs and LCPs. Siesler et al.[68–71] have pioneered studies of segmental mobility in liquid crystalline materials using FTIR spectroscopy. Some key results from their studies are discussed in this section.

Time-resolved FTIR spectroscopy was used[69] to study the segmental mobility of low-molecular-weight nematic LCs and a nematic LCP that had one of the LC units in its side-chain. The difference between the reorientation of the free LC and the bound LC was studied using two-dimensional correlation analysis. It was shown that molecules of the LCs reorient as

Figure 6 Synchronous two-dimensional correlation spectra[69] of the relaxation process of prealigned nematic LCs at (a) 45 °C and (b) 48 °C. [Reprinted with permission from M.A. Czarnecki, S. Okretic, H.W. Siesler, *J. Phys. Chem. B*, **101**, 374–380 (1997) Copyright 1997 American Chemical Society.]

rigid units (Figure 6). Within the nematic LCP, only the mesogen and a small part of the spacer directly attached to the mesogen actually reorient; the rest of the spacer and the backbone chain do not move under the influence of the electric field. The low-molecular-weight LCs were found to be unaffected by temperature and prealignment, while increasing temperature and prealignment significantly reduced the relaxation time of the nematic LCP.

In a related study, the laser-induced anisotropy in thin films of cyanoazobenzene side-chain LCPs based on polyesters selectively deuterated at different positions was investigated[71] using polarized FTIR spectroscopy. Analysis of the segmental orientation based on dichroic ratios of characteristic absorption bands showed that in the polyesters with long main-chain spacing, the light-sensitive azo chromophore, the methylene segment, and to a lesser extent the flexible spacer, were all preferentially oriented normal to the laser polarization. The degree of orientation increased with increasing spacer length. For shorter polyesters, only the chromophore and the spacer were aligned. On-line rapid-scan FTIR analyses revealed that the alignment of the aliphatic segments arose simultaneously with the chromophore orientation. The preservation of the photo-induced anisotropy was directly related to the polyester phase behavior by temperature-dependent IR studies.

Segmental mobility of a ferroelectric LCP was studied[70] using time-resolved FTIR spectroscopy and two-dimensional correlation analysis. It was shown that under the influence of an electric field, only the mesogen and a fragment of the spacer reorient with the attached terminal group. The remainder of the spacer and the backbone chain do not reorient. Similar results from IR spectroscopy studies on other side-chain LCPs lead to the conclusion that this behavior is a general phenomenon in LCPs in which the mesogen is attached to the polymer backbone by a flexible spacer. Estimated relaxation times for selected bands reveal that the reorientation rate increases with temperature. This effect was shown to be due to the decrease of the viscosity with temperature and hence temperature was shown not to have an effect on the reorientation mechanism. Based on such results from IR spectroscopy, new liquid crystalline systems can be made readily accessible for rapid correlation between chemical structure and electro-optical properties.

2.4.3 Photoinduced Reorientation in Dye-containing Liquid-crystalline Polymers

The photo-induced isomerization of dyes in LCPs has been widely investigated by researchers. In particular, mesogenic LCPs containing azobenzene moieties show a unique set of properties and have been proposed as media for reversible optical data storage.[72] Continuous irradiation with polarized light leads to a reorientation of the optical axes. Knowledge of the interactions between the isomerizing dye and the highly anisotropic LC environment can provide valuable information for designing optical storage media.

Spiess et al.[73,74] investigated two statistical LC side-group copolymers with 30 and 50 mol % of a mesogenic cyanoazobenzene-containing moiety as one of the comonomers and a cyanophenyl benzoate-containing moiety as the other. IR spectroscopy was used to simultaneously study the orientational behavior of these copolymers. Under continuous irradiation with polarized light above and below the glass transition temperature, T_g, of the polymers, both the azobenzene and phenyl benzoate side groups preferentially reorient normal to the plane of the film, leading to a strongly biaxial orientation distribution (Figure 7). The kinetics of reorientation are revealed to be a single exponential process,

Figure 7 Order parameter for the azobenzene unit in a copolymer as a function of irradiation time.[74] The squares represent 298 K, the triangles 293 K, and the circles 263 K. All temperatures are below the T_g, which is 303 K. [Reproduced from U. Wiesner, N. Reynolds, C. Boeffel, H.W. Spiess, *Liq. Cryst.*, **11**, 251–267 (1992) by permission of Taylor & Francis Ltd.]

and an additional term is included for the azobenzene dye and is assigned to the initial *trans*-to-*cis* isomerization step. Studies performed on isotropic copolymer systems with azobenzene-containing side groups show that temperature-dependent anisotropy can be induced through irradiation with polarized light.

2.4.4 Phase Characterization/Transformations

The microstructural transformation and dynamics that accompany both monotropic[75] and enantiotropic[76,77] LCs have been of great interest to researchers. The use of vibrational spectroscopy has provided important information at the molecular level on phase transformations and dynamics in LCPs. MacKnight et al.[75] have used IR spectroscopy together with DSC and wide-angle X-ray scattering (WAXS) to study microstructural changes occurring in the different phases of mesogen-containing polyurethane elastomers. Their studies show that the mesophase-to-crystal exothermic transition is accompanied by an increase of H-bonding between the C=O and the NH groups. The crystal melting transition is accompanied by the disappearance of ordered H-bonded amide peaks.

IR spectroscopy has been used to study H-bonding effects[78] in a nematic liquid crystalline poly(ester amide). The NH stretching vibrations were shown to be stable and resulted in H-bonded structures over a wide range of temperatures. It was however shown that the strength of these linkages was very poor and did not affect the mechanical properties of the material significantly.

IR spectroscopy has been used to obtain important information regarding phase behavior in new classes of materials. For example, polymer-dispersed liquid crystals (PDLCs) are a new class of electro-optic material, with applications ranging from architectural glass to active matrix color projection televisions. PDLCs are composites of low-molecular-weight LC droplets dispersed in a polymer binder sandwiched between two transparent, conducting electrodes. In the absence of an electric field, the symmetry axes of the bipolar droplets are randomly oriented, and the refractive index of the LC droplet is mismatched with that of the polymer, resulting in an opaque appearance. In the presence of an electric field, the director orientation rotates to align the droplet with the field. The refractive index of the droplet and the polymer match and the film is transparent.

Various researchers have used IR spectroscopy to quantify the phase-separated microstructure within PDLCs. West and Ondris-Crawford[79] have incorporated dyes to improve the contrast of PDLC shutters. The dichroic IR absorption of the cyano stretch of the low-molecular-weight LC was used to calculate the composition of the droplets. This information can be used to optimally design films for visible operation.

Koenig et al.[80] used FTIR microspectroscopy to compare the polymer and liquid droplet regions within PDLC films made of three different LCs (E7, 5CB, and ZLI-1957/5) and polyvinylpyrrolidone and poly(methyl methacrylate). Their results showed that thermoplastic PDLC matrixes contain higher amounts of LC droplets than thermoset PDLC matrixes. IR functional group images of a droplet were used to show characteristic textures corresponding to the visual images of the same droplet (Figure 8). Conventional FTIR spectroscopy studies revealed that the C≡N and the CH_2 chain require less energy than the C=C chain to align with the field.

The dynamic behavior of PDLCs under the influence of an electric field has been analyzed[81] by static and two-dimensional IR spectroscopy. The PDLC samples were prepared by polymerization-induced phase separation of a mixture of nematic LC E7 and acrylate. Two-dimensional IR correlation analysis confirmed that the rigid core of the LC reorients as a unit. In addition, the authors showed that the polymer side chain, which exists at the interface between the polymer and the LC, reorients by interacting with the reoriented LC molecules.

3 COMPARISON OF INFRARED MEASUREMENTS WITH OTHER TECHNIQUES

XRD is the most commonly used and relatively accurate method of measuring polymer crystallinity.[11,14,16,18,24,29,30,32,42,43,46,51] XRD measures long-range order or intermolecular order as a result of chain packing. IR measures short-range order or intramolecular phenomena.[4] These two methods do

Figure 8 Two functional group images demonstrating the effect of an applied electric field. The orientation within the droplet changes with the field.[80] [Reproduced from C.A. McFarland, J.L. Koenig, J.L. West, *Appl. Spec.*, **47**(3), 321–329 (1993) by permission of the Society for Applied Spectroscopy.]

not necessarily measure the same crystallinity, since short-range intramolecular order is a necessary condition for long-range order to be present, but not vice versa. Therefore XRD and IR measure two different kinds of crystallinity, and IR can detect repeat units in a crystalline domain that can be undetected by XRD.

DSC measures the amount of heat required to melt a sample, and by using knowledge of heat of fusion of a 100% crystalline sample, the degree of crystallinity can be calculated.[4,25,27,31,39,44,46,49] DSC measures the crystallinity based on the meltable portion of the polymer, and represents a degree of order less than that of long-range XRD. However, the degree of crystallinity measured using DSC does not include the contributions of isolated ordered chains to short-range order. Therefore the method used to measure crystallinity needs to be specified for the reported results to be meaningful.

Raman spectroscopy has been used to characterize crystalline polymers. The Raman effect occurs because of an exchange of energy between the incident photons and the vibrational energy levels of the molecule. In many cases, the magnitudes of Raman shifts in the frequency correspond exactly to shifts in IR frequencies and therefore provide the same information. The differences between Raman and IR spectra provide valuable information, and the greater the symmetry of the molecule, the greater the difference between the two spectra.[4] Nonpolar molecular groupings give rise to strong Raman scattering, and molecules with polar groups give rise to strong IR absorption. Therefore, the vibrations of substituents on the carbon chain of polymers can be most easily studied by IR spectroscopy, and the vibrations of the carbon chain itself can be best studied using Raman spectroscopy.

Solid-state NMR is sensitive to crystal packing environments and has been used to characterize the amide configurations of various polymers such as polyamides.[31] However, these spectra are usually complex to decipher as compared with IR spectra. Along with changes in the carbon chemical shifts, the solid-state nitrogen NMR data show chemical shift changes with respect to chain conformation and packing. Nitrogen analysis, where possible, offers the advantages of simplified spectra and a larger spectral range, leading to better peak separation, but suffers from the disadvantages of low natural abundance and low magnetic susceptibility.

The combined use of neutron scattering and IR spectroscopy on mixed polyethylene crystals provides a very sensitive means of determining chain conformation. This is because the two techniques are complementary to a large extent. Neutron scattering is dependent on chain correlations over a wide range of distances,[19,20,24] while the IR technique is predominantly dependent on nearest-neighbor interactions.[20] These interactions could however extend over a much larger distance depending on the arrangement of the chains. Therefore, in summary, IR is a very valuable tool for analyzing crystalline polymers, and can be used in conjunction

with other techniques to provide complete structural information about the polymer.

ABBREVIATIONS AND ACRONYMS

Infrared (IR) spectroscopy locates the spectral position (frequency) and intensity of absorbed (or emitted) radiation arising from molecular transitions between quantum states associated with the vibrations and rotations of specific chemical groups. Using this technique both qualitative and quantitative information can be obtained on changes in the composition of polymers during degradation. The use of mathematical data-processing techniques and instrumental attachments has enabled considerable progress to be made in this field,[1–3] where changes to the composition of the polymer structure are invariably complex. In conventional IR spectroscopy the light is dispersed and each wavelength is examined separately, whereas the main advantage of Fourier transform infrared (FTIR) spectroscopy is that the signal is multiplexed and each point of an interferogram contains information on all the wavelengths present, enabling all frequencies to be determined simultaneously. The increased speed and higher signal-to-noise ratio of FTIR spectroscopy is the prime advantage in the analysis of complex materials. The use of computational software to obtain difference or derivative spectra enhances the dynamic range. This is of particular value when monitoring polymer degradation, where the main interference is from the nondegraded structure of the polymer. The main disadvantage of IR spectroscopy in identifying and quantifying the functional group changes that take place during polymer degradation is that broad and rather featureless bands are frequently produced. As a consequence it is necessary to resolve individual components by subjecting the sample to a prior chemical treatment, or by the use of coupled instrumentation.

1 INTRODUCTION: CHEMICAL TRANSFORMATIONS DURING POLYMER DEGRADATION

Reference sources on polymer degradation are extensive,[4–9] and a number of journals cover current awareness of the subject area, in particular the specialist journal *Polymer Degradation and Stability*.[10]

The degradation in polymers is an irreversible process in which, of all its possible mechanisms, oxidation is usually dominant. Purely thermal degradation is difficult to achieve because it is difficult to exclude oxygen. This is especially true in processing operations when the polymer introduced as powder, granules or pellets will contain oxygen dissolved in, or occupying the spaces between, particles. According to the literature,[11] the incorporation of one molecule of oxygen per hundred polymer chain repeat units can reduce molecular weight by a factor of two to three, and lead to a total embrittlement of the polymer. Figure 1 illustrates inadequately stabilized PVC roofing that is brittle and opaque after outdoor weathering. Embrittlement itself is underpinned by changes to the crystallinity of the polymer. Hence, IR spectroscopy can provide valuable information on polymer degradation kinetics and mechanisms by identifying oxidation products (functional group changes), changes in molecular weight, and changes in structural order during the process of polymer breakdown.

1.1 Characterization and Analysis of Functional Group Changes

Oxidation results in polymer chain scission, crosslinking and secondary oxidation reactions leading to

Encyclopedia of Analytical Chemistry

Figure 1 Inadequately stabilized rigid poly(vinyl chloride) (PVC) roofing, brittle and opaque following outdoor exposure.

the formation of new functional groups. The mechanism involves a radical chain reaction, comprising initiation, propagation (chain branching, chain scission) and termination (Scheme 1).

1.1.1 Initiation

There is an ongoing debate as to how the initiation step in polymer oxidation arises, but considering the heterogeneous nature of the process it is highly likely that breakdown begins at any impurity centers, weak links, or is due to shear and thermal scission during processing. The key feature of initiation is that macroalkyl radicals are formed, and if initiation does not greatly influence the rate, course or extent of degradation then the former arguments are of little issue here. Furthermore, impurity centers are frequently present at concentrations as low as 0.5 per 1000 polymer repeat units, and as such IR spectroscopy lacks the necessary sensitivity for their characterization/quantification.

$RH \longrightarrow R\bullet$	Initiation
$R\bullet + O_2 \longrightarrow ROO\bullet$ $ROO\bullet + RH \longrightarrow ROOH + R\bullet$	Chain propagation
$ROOH \longrightarrow RO\bullet + \bullet OH$ $RH + \bullet OH \longrightarrow R\bullet + H_2O$	Chain branching
$RO\bullet \longrightarrow$	Chain scission

ROOH = Polymer hydroperoxide
•OH = Hydroxy radical

Scheme 1

1.1.2 Propagation and the Formation of Peroxides, Cyclic Peroxides and Epoxides

Oxygen reacts with polymer macroalkyl radicals to yield polymer peroxy radicals, which abstract hydrogen by intra- and/or intermolecular processes to form polymer hydroperoxides according to Scheme 2. When hydroperoxides are formed they may be identified by the combined absorptions of hydroxy and hydroperoxy groups in the region 3300–3650 cm^{-1}. Figure 2 shows the changes in this region during the irradiation of polybutadiene over 67 h. When degraded over a similar period of time, thermally oxidized polyolefins show hydroxyl/hydroperoxide bands of about half the absorbance values of photooxidized polyolefins. Quantitative determination of hydroperoxides by IR spectroscopy generally shows good agreement with other chemical methods employed for their determination.[12]

Scheme 2

It should be appreciated that polymer peroxy radicals in close positions in the same chain may terminate to

Figure 2 IR spectrum of polybutadiene after 0, 15 and 67 h of irradiation. (Reproduced from Beavan and Philips, *Eur. Polym. J.*, **10**, 593 (1974), Pergamon Press Ltd.)

Scheme 3

form stable cyclic peroxides or epoxides according to Scheme 3.

Carlsson et al. have demonstrated that exposure of preoxidized polyolefin films to SO_2 caused >90% loss in hydroperoxide group IR absorbances.[13] This is illustrated by the subtracted spectra of treated and untreated polyethylene (PE) and polypropylene (PP) films given in Figure 3. In both cases new absorptions appear at 900, 1040 and 1195 cm^{-1}. The reaction of SO_2 with hydroperoxide groups proceeds by two consecutive reactions, depending on the relative ratio of SO_2 to the hydroperoxide groups (Scheme 4). When there is an excess of SO_2, hydosulfates are predominantly formed, but when the local peroxide concentration is dominant dialkyl peroxides are formed. This introduces uncertainty in the measurements and so films are exposed to gaseous NH_3 following SO_2 exposure (Scheme 5). This results in the formation of ammonium sulfate, as evinced by new bands at 1420, 1105 and 620 cm^{-1}. The extinction coefficients of these bands are relatively high and hence afford enhanced sensitivity of OOH detection, despite the variable stoichiometry of reaction. Because SO_2 reacts selectively with hydroperoxide groups, this method may be used to differentiate them from hydroxyl groups.

Figure 3 Subtraction IR spectra of PE (a) and PP (b) films: (———) unoxidized; (- - - - -) after γ-irradiation; (· · · ·) after exposure to SO_2 and NH_3. (Reproduced from Carlsson et al., *Polym. Degrad. Stab.*, **15**(1), 70 (1986), Elsevier Applied Science.)

The collective determination of hydroperoxide and hydroxyl groups may be executed by exposure to nitric

Scheme 4

Scheme 5

oxide (NO) for 2–150 h, depending on the specific polymer sample. Because NO alone produces complex spectra, due to the formation of a variety of nitrates and nitrites, it is more often used in conjunction with sulfur tetrafluoride (SF_4).[14–16] After reaction with NO, the OH and OOH groups are separated by the formation of nitrites and nitrates, respectively. In this way primary, secondary and tertiary products can be resolved; moreover, the molar decadic absorptivity of the NO adducts is significantly higher than the original OH and OOH groups, thereby enhancing detection sensitivity. On addition of SF_4, all types of groups containing a hydroxyl component are fluorinated, with OOH and OH groups being converted to fluorides. On the other hand, reaction with NO_2 produces a complex mixture of products, with strong absorptions at 1700, 1300 and 925 cm^{-1} due to the formation of nitric acid.[16]

In addition, absorptions of hydroxyl groups may be separated from hydroperoxide groups by reaction with either diisopropoxytitanium bis(acetylacetonate) or chloroacetyl chloride (Scheme 6).[17]

Scheme 6

1.1.3 Chain Branching and the Formation of Carbonyl Groups

Carbonyl groups are formed during the chain-branching steps of oxidation. Thermolysis and/or photolysis of hydroperoxides results in the formation of polymer oxy radicals, which participate in β-scission reactions of the polymer chain to form either ketone or aldehyde groups and a radical chain-end (Scheme 7).

The acids, ketones, aldehydes, esters and lactones produced in such oxidation steps result in broad and rather featureless bands extending from 1650 to 1850 cm^{-1} (Figure 4). Kato et al. have shown that such a typical band may be resolved into six overlapping peaks (Figure 5).[18] For precise quantitative determination of specific groups it is necessary to separate the individual absorptions. The absorptivity of acid groups has been reported to be 2.4 times greater than that of ketones and 3.1 times greater than that of aldehydes.[19] Rugg et al.[20] have demonstrated that during thermal oxidation the carbonyl groups produced are predominantly ketonic, whereas during photooxidation roughly equal quantities of acid ketone and aldehyde groups are formed. Using FTIR

Scheme 7

Figure 4 IR spectra of the photooxidation products in PP film after irradiation for 0 (I), 6 (II) and 110 h (III). (Reproduced from Wiles, *Polym. Eng. Sci.*, **13**, 74 (1973), Society of Plastics Engineers.)

Figure 5 Composition of the carbonyl absorption of photooxidized PP film. (Reproduced from Kato et al., *J. Appl. Polym. Sci.*, **13**, 1447 (1969), John Wiley & Sons.)

Figure 6 IR spectra of photodegraded PP (a–e) and PE (f–j) following various treatments. FS/BL exposure = fluorescent sun lamp/black lamp. (Reproduced from Adams, *J. Polym. Sci. Polym. Chem. Ed.*, **8**, 1279 (1970), John Wiley & Sons.)

spectroscopy, Tabb et al. have shown that the concentrations of aldehyde groups decrease during the photooxidation of PE, but that the ketonic groups increase.[21]

For polyolefins, the identification and analysis of the various groups comprising the carbonyl band has been achieved by various chemical treatments, as summarized in Figure 6.[22] Films may be placed in a vacuum oven to remove volatile products, but this does not resolve the carbonyl band. Extraction of the polymer with isopropanol removes part of the carbonyl absorption, leaving a narrow band centered at 1740 cm^{-1} that may be assigned to ester groups. The absorption band at 1790 cm^{-1} is attributed to γ-lactone and that at 1715 cm^{-1} to carboxylic acid. Treatment of the films with a base converts the lactones, esters and carboxylic acids to carboxylates, which shifts the main absorption band to 1580 cm^{-1}, leaving a small band at 1720 cm^{-1} due to aldehydes and ketones. Upon acidification of the base-treated polymer samples, the orginal esters absorbing at 1740 cm^{-1} are not regenerated but are converted into free acids. On this basis it was shown that during the photooxidation of PE only ketones were observed, but for PP both ketones and aldehydes were shown to be present. The carbonyl group of a carboxylic acid may be distinguished from that of a ketone by the addition of molar sodium hydroxide, which results in

the formation of a new band due to the carboxylate anion at 1580 cm^{-1} as the carbonyl band at 1715–1720 cm^{-1} is reduced.

The broad carbonyl absorption may be resolved better by chemical derivatization methods. Keto groups may be differentiated from aldehyde groups by tagging with specific reagents, namely pentafluorophenyl hydrazine and 2,4-dinitrophenyl hydrazine (Scheme 8).[23] In each case the ketone absorption at 1720 cm^{-1} is reduced and a new band due to C=N appears at 1650–1690 cm^{-1}. This is useful as a measure of oxidation but to isolate a wider range of carbonyl groups a more sophisticated approach is required.

Scheme 8

Scheme 9

Lacoste et al. employed γ-irradiation to produce a simple and controlled mixture of polyolefin oxidation products, and compared this with thermally or photo-oxidized polyolefins.[24] Films were treated with NO followed by SF_4 to monitor changes in both carbonyl and hydroperoxide groups (Scheme 9). To enable accurate measurement of IR absorbances, films were tilted at the Brewster angle and a polarizer placed in the beam, which according to Harrick eliminated the interference ripples that arise from polymer films.[25] Figure 7 shows LLDPE films after oxidation and following derivatization. For NO-treated samples, nitrate peaks centered at 1276 and 865 cm^{-1}, corresponding to secondary hydroperoxides, are seen as negative peaks following spectral subtraction. A nitrite peak at 778 cm^{-1}, indicative of secondary hydroxyl, is positive after subtraction. The negative

Figure 7 FTIR changes in linear low-density polyethylene (LLDPE) films before and after derivatization: (a) after 96 h of thermal decomposition at 85 °C; (b) after 10 Mrad of γ-irradiation; (c) after 69 h of xenon arc exposure. (Reproduced from Carlsson et al., *Polym. Degrad. Stab.*, **34**, 309–323 (1991), Elsevier Applied Science.)

peaks at 1632 cm^{-1} are characteristic of a mixture of these previous absorptions. On treatment with SF_4, a band due to acid fluoride at 1848 cm^{-1} is produced by reaction with carboxylic acid end-groups. Heacock had previously observed this latter absorption, but centered around 1835 cm^{-1}.[26] This greatly simplifies the carbonyl region, allowing ketone, ester and γ-lactone absorptions to be distinguished.

1.1.4 Unsaturated Groups

If hydroperoxides are incorporated adjacent to unsaturated impurities, then α,β-unsaturated carbonyl groups will result (Scheme 10). The α,β-unsaturated carbonyl groups so formed may isomerize to give β,γ-unsaturated carbonyl groups according to Scheme 11. Carbonyl groups may be photolyzed by Norrish Type I and II processes to yield: in the former case, carbon monoxide and a further radical chain-end; in the latter case, end-chain vinyl groups and carbonyl groups (Scheme 12).[27]

Scheme 10

Scheme 11

The formation of unsaturated groups is best illustrated by reference to polyolefin oxidation (Figure 8). Rueda et al. have used IR spectroscopy to measure vinyl, vinylidene and internal *cis* or *trans* olefinic end-groups in PE, which can be used as a basis to identify any changes in these groups.[28] Prior to photooxidation, PE exhibits both vinyl and vinylidene at 909 cm^{-1} and

Scheme 12

Figure 8 IR spectrum of low-density polyethylene (LDPE) (10-mL film, molecular weight = 10 000) before (A) and after (B) photooxidation. (Reproduced from Rugg et al., *J. Polym. Sci. Polym. Chem. Ed.*, **13**, 535 (1977), John Wiley & Sons.)

887 cm^{-1}. During irradiation the vinylidene groups are destroyed and the vinyl content increases, in parallel with carbonyl formation (Figure 9).[29]

In other polymers, such as PVC, thermal oxidation results in the formation of carbonyl groups and poly-conjugated sequences of double bonds. Figure 10 shows changes in the IR spectrum of a PVC film subjected to thermal oxidation at 140 °C over 160 h.[30] A broad carbonyl band is evident between 1650 and 1850 cm^{-1}, and overlapping this is a peak due to the development of unsaturation centered at 1605 cm^{-1}. Dienes and trienes usually absorb around 1650–1600 cm^{-1}, whereas the band for polyenes is shifted to lower wavenumbers (1650–1580 cm^{-1}). Although IR spectroscopy is able to detect the presence of unsaturation and indicate that

Figure 9 Change in the composition of functional groups in LDPE. (Reproduced from Amin et al., *Eur. Polym. J.*, **11**, 85 (1975), Pergamon Press.)

Figure 10 Changes in the IR spectrum of a PVC film before (A) and after being submitted to thermal oxidation at 140 °C for (B) 20 h, (C) 45 h, (D) 70 h, (E) 90 h, (F) 160 h. (Reproduced from Gardette et al., *Polym. Degrad. Stab.*, **34**, 149 (1991), Elsevier Applied Science.)

polyene sequences of varying length are formed, by the broadening of the IR band, it is unable to give information on the length of the polyene sequences.

In contrast, for polymers already containing significant unsaturation, such as polydienes, IR spectroscopy has been useful in distinguishing different types of unsaturation and how important different double bonds are in thermal oxidation mechanisms. In this respect, Brako and Wexler have exposed polybutadiene films to bromine vapor, noting the resulting marked changes (Figure 11).[31] By this treatment, bands at 730, 910, 965

Figure 11 IR spectra of polybutadiene before (·····) and after (———) exposure to bromine vapor. (Reproduced from T.R. Crompton, *Analysis of Polymers: an Introduction*, 92, 1989, Pergamon Press.)

and 1640 cm^{-1} associated with unsaturation are reduced and new bands associated with bromination of double bonds appear at 550, 785, 1145 and 1250 cm^{-1}.

Other workers have also capitalized on this methodology for PE. Unsaturation in LDPE has been estimated as ± 0.003 C=C 10^{-3} carbon atoms by compensating with brominated polymer of the same thickness.[32] Dankovics has determined the total degree of unsaturation in LDPE as the sum of vinyl, vinylene and vinylidene groups, using difference spectra between an unbrominated polymer film (sample) and a brominated film (reference).[33]

1.1.5 Propagation and the Formation of Acids and Peracids

Any end-of-chain aldehyde groups may react with polymer peroxy radicals to produce polymer acyl radicals. The acyl radicals may be oxidized further to peracid radicals, which can hydrogen abstract to form polymer peracids, with IR absorptions centered at 3280, 1785 and 950 cm^{-1}. In turn, cleavage of the peracid groups results in the formation of carboxylic acids at 1710 cm^{-1} (Scheme 13).

1.1.6 Chain Scission and Cross-linking

Chain scission may be determined directly by the production of new functional groups and chain-ends in the polymer, and indirectly as a reduction in the molecular weight of the polymer (see section 1.2). Cross-linking reactions result from termination reactions, and may link polymer chains or chain fragments either without or with the incorporation of oxygen. In the latter case this will result in the formation of a peroxide group or an ether group (Scheme 14). Cross-linked material is frequently intractable in nature, as such direct identification by IR spectroscopy is often not possible and it

Scheme 13

Scheme 14

is necessary to resort to more sophisticated techniques (refer to section 5.1).

1.2 Changes in Molecular Weight

IR measurements of molecular weight depend largely on the detection of end-groups. Here, a number-average molecular weight may be found, provided that the polymer chain is linear with few branch points. This is of particular value when examining the hydrolytic or oxidative degradation of condensation polymers. Low-molecular-weight analogs may be used to calibrate the spectra, because in polymer chains, end-groups are not coupled to the main chain. Figure 12 illustrates the IR spectra of two samples of poly(butylene terephthalate) of different molecular weight.[34]

In some instances end-groups give intense and readily observable vibrational absorptions. This is the case for PE terminal vinyl groups (909 and 990 cm^{-1}). Such groups are detectable because their dipole moment is stronger

Figure 12 IR spectra of two samples of poly(butylene terephthalate) with different molecular weights. (Reproduced from Kosky et al., *Polym. Eng. Sci.*, **25**, 389, 1985.)

than those of constituent methylene wagging and twisting modes. The absorptions of end-groups can be accentuated by subtracting a high-molecular-weight polymer spectrum from the spectrum of a low-molecular-weight analog.

However, this approach is not applicable to many polymers where absorptions of end-groups may be weak. For example, methyl end-groups at 1379 cm^{-1} not only give rise to a weak absorption but are overlapped by a larger number of amorphous methylene modes located in the same region of the IR spectrum. Furthermore, IR spectroscopy cannot provide direct information on the distribution of species of differing molecular weight that may be present in a degraded sample. To identify the different oligomeric fractions produced during polymer degradation, gel permeation chromatography (GPC), in combination with FTIR spectroscopy, and using a flow-cell technique is useful.[35] Thin flow cells with very small internal volume (10 μL), allowing better solvent transmission and suppressing peak broadening, can be used for detection. Here, the FTIR system transforms and displays spectra in real-time during the chromatographic procedure. Furthermore, absorbance subtraction techniques may be used to explicate the composition of chromatographically unresolved components.

1.3 Structural Order and Degradation

It is widely accepted that the degree of crystallinity of a polymer has a marked affect on its rate of oxidation.

Generally, reactivity between free radicals and oxygen is higher in regions of low crystallinity (amorphous regions) owing to the higher segmental mobility of chains, whereas in highly crystalline regions radical recombination is promoted.

However, great care should be taken when attempting to use IR spectroscopy to elucidate structural order in polymers. Maddams has stated that ''Peaks should not be designated as crystallinity bands unless they disappear on melting, are predicted by group theory and are shown to depend upon the existence of a crystal lattice''.[36] Even when bands may be attributed decidedly to crystallinity, the relative intensity of such bands may be due to orientation in addition to crystallinity. This is the case for PE, where the doublet at 720/730 cm^{-1} is a function of both crystallinity and orientation (Figure 13). In this sense IR spectroscopy is a poor substitute for X-ray diffraction and dielectric loss spectroscopy. Crystallinity is itself influenced by the degree of chain branching and by the length of the branches formed. Again, IR methods are of limited value in comparison with other techniques, notably nuclear magnetic resonance (NMR) spectroscopy, when it comes to assigning specific branches.[2] However, an IR scale of branching is still widely used by polymer manufacturers owing to the relative expense of high-resolution NMR methods.

Morphological changes in semicrystalline polymers, brought about by the application of mechanical stress, depend on their original morphology, in particular the degree of orientation. It is believed that any imposed stress reduces the probability of radical recombination at a site of bond rupture. This has been supported by a study of the rupture of stressed bonds as the first to be broken, as demonstrated by shifts in IR absorption bands to lower wavenumbers.[37–39]

Extensive studies have confirmed that orientation results in a reduction of segmental mobility and the sorption and diffusion of gases in the polymer matrix brought about by closer packing of the amorphous fraction. Figure 14 illustrates the use of IR spectroscopy to study how changes in the orientation of polymer chains – of varying draw ratio – influence the rate of oxidation, as evinced by carbonyl formation at 1715 cm^{-1}. This study revealed that for a given draw ratio, the oxidative degradation of high-density polyethylene (HDPE) was retarded with an increase in drawing temperature.[40]

If orientation of polymer chains has a bearing on oxidative stability then dichroic and trichroic measurements of orientation of polymers are likely to be of value in establishing which orientational isomers confer stability to a given polymer and, more specifically, in establishing relationships between orientation and mechanical properties.[2] Here the polymer axis is aligned parallel, perpendicular or through the film thickness to the spectrometer sampling plane.

2 QUANTIFICATION OF FUNCTIONAL GROUPS AND THE KINETICS OF POLYMER OXIDATION

IR spectroscopy remains a fundamental technique for the study of the kinetics of polymer oxidation. A considerable number of studies have been undertaken on the kinetics of the thermal and photooxidation of polyolefins. The rates of formation of nonvolatile products under various experimental conditions may be derived from the formation of carbonyl groups as a function of temperature and oxygen concentration. The activation energies for the major oxidation stages of polymers may be estimated from various Arrhenius plots.

Stivala et al. have used IR spectroscopy to study the continuous oxidation of polyolefins.[41] To achieve this, a temperature-controlled cell was constructed to allow constant monitoring of a polymer film undergoing oxidation. The relative concentration of carbonylic products formed when the ratio of oxygen to nitrogen impinging on the polymer film was varied is given at different temperatures. Plots of area under the carbonyl band as a function of time at various temperatures were sigmoidal in shape, the maximum slope giving the rate of carbonyl formation. This is a manifestation of the autocatalytic nature of the oxidative process.

In order to correct for variations in sample thickness, it is usual to measure the intensity of a particular band relative to some other band, the intensity of which does not vary during the course of degradation. The resulting ratio is defined as a specific functional group index. The most widely employed of such indices is the so-called carbonyl index.[9] This index is used for the indirect determination of embrittlement time in polyolefins, which is taken as the time in hours to achieve a carbonyl index of 0.06. The carbonyl absorbance intensity is compensated for by the ratio of its value to film thickness or the intensity of an internal reference peak. In PE, the methylene wagging-mode centered at 1369 cm^{-1} may be used as the reference (Figure 15).

3 ROLE OF ANTIOXIDANTS IN POLYMER DEGRADATION

In general, antioxidants are added to polymers to inhibit the radical reactions taking place.[5–9] They may be classified as radical scavengers, peroxide decomposers, metal deactivators, color inhibitors, acid scavengers and ultraviolet absorbers. These compounds are usually added during processing at levels 0.05–0.2% w/w of the polymer. During aging, these additives may experience either facile loss from the polymer or be transformed by reaction with the degrading polymer matrix.

IR spectroscopy is more specific than ultraviolet spectroscopy, but frequently additive levels are too low to give suitable spectra. Despite this it is one of the most commonly used direct methods for additive analysis in polymers. The mid-IR range (4000–400 cm^{-1}) has been most widely used, e.g. the carbonyl groups of phenolic antioxidants at 1740 cm^{-1} and the oxygen phosphorus–phenyl groups of phosphite antioxidants at 890 cm^{-1}. Figure 16 illustrates calibration curves for IR determination of the antioxidants Irganox 1010 and Irgafos 168.[42]

Alternatively, time-consuming chemical separation of multicomponent systems may be replaced by obtaining difference IR spectra. This applies to systems where one or more components occur in small concentrations. Once the spectrum of a standard ''pure'' polymer has been obtained, it can be used to remove the base (polymer) spectrum from that of the modified polymer sample.

Figure 16 FTIR spectra of a set of PE calibration standards formulated with varying levels of Irganox 1010 and Irgafos 168. (Reproduced from Tikuisis, *Plastics Additives: an A–Z Reference*, 91, 1998, Chapman and Hall.)

Miller and Willis obtained IR spectra of antioxidants in polymer films by compensating with an additive-free polymer in the reference beam.[43]

Owing to interference effects by extraction solvents, other additives and adventitious impurities in the polymer, direct IR spectroscopy of polymer extracts has found very limited application in the determination of additives. However, when IR spectroscopy is preceded by a clean-up or separation technique, such as thin-layer chromatography, then it is an extremely useful method for both characterization and analysis. Spell and Eddy have described IR procedures for the determination of additives, at concentrations up to 500 ppm, in PE pellets following solvent extraction with carbon disulfide at room temperature for 2–3 h.[44]

Development of a calibration curve for the quantitative determination of an antioxidant by IR analysis can be difficult. Unlike chromatographic analysis, where calibration only requires the gravimetric dissolution of the antioxidant in an appropriate solvent, IR analysis requires the antioxidant to be dispersed homogeneously throughout the polymer matrix at the correct concentration.

Near-infrared (NIR) analysis is able to circumvent problems of additive dispersion. NIR has lower absorptivity than conventional mid-IR radiation, which enables it to penetrate more deeply into a polymer sample. Because of this, slightly inhomogeneous additive distributions are less problematic. Furthermore, because glass does not act as a cut-off filter for NIR, fiber optics may be employed to probe antioxidants directly in a polymer melt stream during processing.[45]

Rather than studying the antioxidants themselves, an alternative approach is to study changes to the mechanism or rate of oxidation of the polymer itself in the presence or absence of an antioxidant. The reflectance IR spectroscopic study by Chan and Allara, of the oxidation of PE coated on to a copper substrate in the presence and absence of the metal deactivator *N*,*N*-diphenyloxamide, illustrates this approach.[46]

4 TECHNIQUES

4.1 Pyrolysis Gas Chromatography and Infrared Spectroscopy

The IR spectra of gas chromatographic effluents may be taken from gaseous samples or from liquid samples by

Figure 17 FTIR spectrum of gaseous combustion products of a PVC composite at 648 K in air. (Reproduced from Liebman et al., *Appl. Spectrosc.*, **30**, 355, 1976.)

trapping techniques. Because analysis in the gas stream eliminates the difficulties associated with condensing vapor-phase degradation products, it is considered more desirable. Furthermore, this latter technique holds most value when monitoring the toxic gases associated with the degradation of polymers caused by combustion (Figure 17).[47] Here, fast-scanning FTIR spectrometers may be interfaced to a flow-through heated light-pipe gas cell to allow the continuous measurement of any volatile effluents.

The difficulties associated with the identification of intractable, cross-linked material produced during degradation may be overcome by spectroscopic examination of liquid and gaseous pyrolysis products along with any involatile residues. The IR spectra of gas chromatographic effluents may be taken either from liquid (trapping technique) or gaseous samples. Analysis in the gas phase is desirable because this approach eliminates the difficult process of preferentially condensing the sample from a vapor stream. The advantage of this approach is the selectivity of IR spectroscopy when combined with the separation capacity of gas chromatography. However, when the highly cross-linked material is a vulcanizate, pyrolysis IR methods have limited value.[48] A more useful approach is thermal volatilization analysis, which, being nondestructive of the various product fractions that it produces, lends itself readily to further IR analysis.[49–55]

4.2 Attenuated Total Reflectance

Whether the degradation is typically thermal or thermo-oxidative depends on the relative rates of the two reactions given in Scheme 2. Under processing conditions, because access to air is restricted and at high temperatures oxygen solubility is low, higher concentrations of macroalkyl radicals are likely to be present and reactions such as depropagation (of monomer), radical chain transfer and chain scission dominate. Normally a steady state is rapidly established, but there are two main exceptions to this. The first takes place in very thin films where the rate of diffusion of volatile products results in a nonsteady-state process, preventing side reactions between the volatile products and chain radicals. The second occurs during the extrusion of a hot polymer into air, where oxygen ingress is diffusion-controlled, giving rise to oxidation reactions in a surface layer only a few microns thick. The depth of oxidation in a thick-section material is an important parameter, influencing its mechanical properties. In this respect the ability of IR spectroscopic techniques, such as attenuated total reflectance (ATR) and microtoming, in profiling the extent of degradation is of considerable industrial importance.

Stivala et al. found that the rate of oxidation in atactic PP was constant for films of thickness up to 8.6 μm but decreased for films of 19 μm. These authors found a linear relationship between the band at 1380 cm^{-1} and film thickness. Hence, this band may be used as an internal sample for PP films of varying thickness.[56]

Information on the distribution of chemical structure of polymers in the depth direction may be achieved in several ways.[57,58] Samples may be cut obliquely with a microtome into films of typical thickness 1–2 μm. This increases the apparent depth, i.e. when the cutting angle is 1° the length of the cutting surface is 50 times the corresponding depth (Figure 18). The thin films produced may then be analysed in the depth direction by IR microspectroscopy operating in transmittance mode.

For opaque samples, or when samples are difficult to cut into thin films, perhaps due to embrittlement during degradation, ATR may be employed. Adaptations of the basic ATR method are particularly useful when studying the degradation of highly filled polymers, where the process of multiply-disturbed total internal reflection

Figure 18 Schematics of the principle of depth analysis and the prism developed for ATR IR microspectroscopy. (Reproduced from Murase et al., *Polym. Degrad. Stab.*, **43**, 416, 1994, Elsevier Science.)

is of value.[59] Here the sample is placed in intimate contact with a crystal of high refractive index and low IR absorption. The IR beam undergoes a series of multiple reflections, which are a function of the length of the crystal. The main advantage of this method is that not only does it permit the analysis of opaque samples but it also allows the signal-to-noise ratio to be optimized. In general, by correct choice of the reflection device, and hence the angle of incidence of IR radiation impinging on the sample, it is possible to record ATR spectra to various depths of penetration of the IR beam into the surface of the sample. Hence, by using this technique a limited ''concentration profile'' of specific groups associated with the polymer or polymer additives may be assimilated.

4.3 Diffuse Reflectance Infrared Fourier Transform Spectroscopy

Recent developments in the diffuse reflectance infrared fourier transform (DRIFT) technique have further enabled the depth profiling of surfaces and in addition the study of interfaces.[60–62] Here, the uppermost surface of the sample is covered with a layer of powdered KBr, such that as the thickness of this powdered layer is increased, the ratio of surface-to-bulk contribution to the spectrum increases.

4.4 Photoacoustic Spectroscopy

This technique has the advantage in that it allows IR spectra to be obtained for samples that are difficult to prepare as transparent films, where the sample has high internal light scattering and for samples that are coated on to opaque or strongly light-scattering substrates. Figure 19 illustrates photoacoustic spectroscopy (PAS) spectra of Kevlar fibres before and after removal of the outer layer by oxidation.[63]

4.5 Fourier Transform Infrared Emission

IR emission spectroscopy enables easy acquisition of spectroscopic information from samples undergoing degradation at elevated temperatures, by detecting the time-dependent IR emission originating from polymers as they deteriorate. DeBlase and Compton provide a detailed review of emission spectroscopy.[64] These

Figure 19 Photoacoustic spectra pertaining to the relative emissivity of Kevlar-49 fibres before (a) and after (b) oxidation. (Reproduced from Koenig et al., *Makromol. Chem.–Makromol. Symp.*, **5**, 99, 1986, Hüthig & Wepf Verlag.)

authors describe a process whereby IR emissions from a moving sample may be collected when the surface of the sample has been quickly heated or cooled by a jet of hot or cold gas. This process induces a thermal gradient across a thin film of sample and, as such, has distinct advantages for industrial applications. George et al. have investigated the thermal oxidation of polyolefins by monitoring carbonyl band growth as a function of degradation time.[65,66] Using this method it was possible to infer the heterogeneous nature of the degradation process. Celina et al. have recently applied FTIR emission spectroscopy to the study of in situ polymer degradation.[67,68] In Figure 20(a) and (b) the emittance and changes therein are depicted for polystyrene oxidized at 220 °C.

It should be noted that for quantitative measurements careful referencing of spectra to an instrumental background is necessary to obtain band-specific relative emission intensities. For bands with high emittances, quantitative measurements are difficult due to the uncertainty in determining values close to band saturation. In addition, this technique is not suited to carbon-black-filled materials, because featureless blackbody emission is observed, although other highly filled systems may be studied.

5 ADVANTAGES AND LIMITATIONS OF INFRARED METHODS

By reference to the various examples discussed above it is obvious that IR spectroscopy is widely used in the study of polymer degradation. One of its main advantages in direct analysis is its speed and convenience. Ironically, it is limited in the study of polymer degradation because it is so very matrix-dependent. The complexity of the polymer degradation mechanism(s) results in a large number of functional group changes that lead to the broadening of IR bands. Fortunately, this lack of selectivity during direct analysis has been largely circumvented. Over the last few decades the development of chemical derivatization methods has enabled overlapping absorptions to be resolved. Furthermore, the use of attachment devices has allowed easier handling of friable samples and the depth profiling of samples, and computational methods such as spectral subtraction have led to enhanced sensitivity. Despite this evolution in methodology, IR spectroscopy remains limited in some respects. In the evaluation of microstructural changes it cannot effectively compete with NMR or Raman spectroscopy, nor is it able to define adequately the morphological changes, as X-ray diffraction can.

Overall, the interfacing of FTIR with other instruments offers the best way forward to the study of polymer degradation. A pertinent example to illustrate this is vapor-phase IR spectroscopy employing fast-scanning techniques, as used by Kiran and Gillham.[69,70] The system, composed of a programmable pyrolyzer, thermal chromatogram, mass chromatogram and fast-scan vapor-phase IR spectrometer coupled to a computer, is able to provide a profile of the thermal history of the sample prior to and during pyrolysis. The integrated system is able to determine the relative amounts of volatile and nonvolatile degradation products from the resulting chromatographic retention times, IR spectra and mass numbers.

Infrared (IR) spectroscopy is the measurement of the intensity of IR radiation absorbed at specific wavelengths, which can be used for the characterization of solid, liquid, gas, fiber, and powder samples. This technique allows molecular level identification of surface, interfacial, and bulk regions owing to its high selectivity and sensitivity. Quantitative measurement of molecular functionalities is accomplished by comparison with standards of known concentrations. The IR spectroscopic methods covered in this article include transmission, internal reflectance, reflection–absorption, diffuse reflectance, photoacoustic (PA), and step-scan techniques. Common applications of IR spectroscopy include polymer blending, adhesion, surface analysis, kinetics, and multidimensional studies.

The molecular specific information IR spectroscopy provides is one of the most useful aspects of this technique when compared to other common analytical methods. Compared with gas chromatography/mass spectrometry (GC/MS) which reaches parts per billion detection limits, IR spectroscopy, which is much less sensitive, provides nondestructive analysis. The depth resolution of X-ray photoelectron spectroscopy (XPS) and Auger electron spectroscopy (AES) is several orders of magnitude better than IR spectroscopy, yet the ultrahigh vacuum (UHV) operating conditions of these techniques would destroy volatile samples. While the lateral resolution of scanning electron microscopy (SEM), energy-dispersive X-ray analysis (EDX), and transmission electron microscopy (TEM) techniques is superior to IR spectroscopy, these methods require tedious sample preparation. IR spectroscopy offers sensitivity to a wide range of samples with limited sample preparation needed.

1 INTRODUCTION

Vibrational spectroscopy is a powerful analytical tool for identification and characterization of organic molecules. IR spectroscopy measures the amount of radiation absorbed at specific wavelengths corresponding to distinct vibrational motions of molecular bonds. By analyzing the IR radiation absorbed or transmitted by a sample, the characteristic functional group vibrations can be deduced, and the molecular composition can be identified from the resulting IR spectrum. This ''fingerprint'' spectrum provides unique information about molecular structure and chemical bonding. There are numerous publications on vibrational spectroscopy which include IR

theory, instrumentation, data interpretation, and polymer characterization.[1–8]

The energy levels in IR spectroscopy are commonly represented as wavenumbers ($\bar{\nu} = 1/\lambda$), expressed in units of cm^{-1}. The IR region is divided into three sections: the near-IR ($\bar{\nu} = 12\,820–3333\,cm^{-1}$), the mid-IR ($\bar{\nu} = 3333–333\,cm^{-1}$), and the far-IR ($\bar{\nu} = 333–33\,cm^{-1}$) regions. The near-IR region involves overtone and combination bands of the mid-IR fundamental vibrations, which are often overlapping, making interpretation difficult. The far-IR region is difficult to study owing to energy limitations of Nernst glower sources, beamsplitters, and detectors, as well as background gas absorptions. The majority of the useful molecular information in IR spectroscopy is contained in the mid-IR region, although the near- and far-IR regions have found useful applications as a result of new developments in chemometric analysis.

IR spectroscopy is straightforward in terms of experimental design, instrumental maintenance, and operating expenses. Owing to high selectivity and sensitivity at the molecular level, IR spectroscopy has become a very capable analytical technique for understanding polymeric structure.[9–11] IR analysis produces molecular-specific identification of a wide range of samples, including solids, liquids, gases, fibers, and powders, at a minimum measurable absorbance of 0.001 AU (absorbance unit).[12] With proper sampling techniques, the surface, interfacial, and bulk regions of a sample can be studied.

The main limitation of IR spectroscopy is quantitative analysis. Absolute measurement of specific functionalities requires extensive sample preparation and is often prone to artifacts due to optical effects.[13] This can be overcome by comparison with standards of known concentrations, but sample preparation is crucial to success analytical analysis.

2 HISTORY

IR spectroscopy has been used in polymer characterization for many years. In the simplest form, IR spectroscopy is based on transmitting IR radiation through a sample and measuring the absorption. This was initially accomplished with a dispersive instrument using a prism or grating to scatter the IR radiation, as shown in Figure 1. By using a calibrated scanning mechanism, specific frequencies of interest can be isolated and the dispersed radiation recorded. From this method, the energy transmitted through a sample as a function of frequency can be obtained.

Dispersive IR analysis was replaced by Fourier transform infrared (FTIR) spectroscopy, where IR energy is collected in the time domain and Fourier transformed to the frequency domain. As shown in Figure 2, this interferometric method involves dividing the IR light into two separate paths by passing through a beamsplitter. By reflecting the IR light back along the same optical path, the energy is recombined in a constructive or destructive manner at the beamsplitter, forming the basis for interferometry. The detected energy as a function of optical path difference, also known as an interferogram, is Fourier transformed to the frequency domain. The resulting FTIR spectrum represents IR energy transmitted through a sample as a function of frequency.

The introduction of the Michelson interferometer, and subsequent FTIR instruments, vastly improved IR spectroscopy owing to several factors: the Fellgett (multiplex advantage), Jacquinot (throughput advantage), and Connes (frequency advantage).[14] The Fellgett

advantage arises from the fact that the FTIR spectrometer examines the entire spectrum in the same time period required for a dispersive instrument to examine a single spectral element. For similar measurements, the signal-to-noise ratio (S/N) of spectra from FTIR will be $n^{1/2}$ times greater than a grating instrument, where n is the number of resolution elements being examined during the measurement. This equates to a 60-fold increase in S/N for FTIR instruments. Spectroscopists have taken advantage of this factor in the study of polymer kinetics,[15] degradation,[16] and other time-dependent processes,[17,18] where S/N improvements are critical.

The Jacquinot advantage results from more effective throughput of the radiant power of the source with a Michelson interferometer, although the throughput for FTIR instruments is limited by the size of the mirrors.[19,20] Higher throughput is particularly important in trace analysis where the IR response is typically weak.

The Connes advantage arises from the fact that the frequencies are internally calibrated with an He–Ne laser for an FTIR instrument, whereas calibration of gratings in dispersive instruments is less reliable and has a tendency to drift.[21] Since co-adding of spectra is routinely done to improve S/N, frequency accuracy is an absolute requirement.

3 FOURIER TRANSFORM SAMPLING METHODS

Although many analytical techniques are suitable for surface analysis, there are inherent limitations to be aware of. The UHV operating conditions of secondary ion mass spectrometry (SIMS), XPS, and AES will destroy volatile samples unless special precautions are taken, such as a low-temperature sampling stage. Likewise, techniques such as SEM, EDX, and TEM require tedious sample preparation. FTIR offers surface sensitivity for a wide range of samples, without limitations on sample analysis. The various sampling methods commonly used in FTIR studies of polymers are shown in Figure 3. These spectroscopic methods include transmission, internal reflectance, reflection–absorption, diffuse reflectance, PA, and step-scan.[22–27] The sampling capabilities of these techniques are summarized in Table 1.

3.1 Sample Preparation

In order to analyze polymer specimens fully with FTIR, proper sample preparation is essential. Common preparative techniques have been reviewed by Haslam and Willis.[4] The preparation method is generally determined by the type of information required and the sample stability. A solid polymer sample can be prepared for transmission FTIR by mulling in liquid paraffin (Nujol), cast from the melt or a solution, or grinding with a powder and compressing into a disk. Disks are prepared with IR-transparent halide salts such as KBr, CsI, and NaCl, which will lose less spectroscopic information. Although these techniques yield films of high spectral quality, the process is destructive and the processing history of the sample is lost. An alternative method is a diamond cell where the solid sample is placed between two flat diamond surfaces.[28] A screw closes the diamond surfaces, compressing the sample to a suitable sampling thickness.[29] The diamond cell is used to study fiber and powder samples.[30]

3.2 Transmission Fourier Transform Infrared Spectroscopy

In spite of the development of reflective methods, transmission measurements remains the most commonly used technique, particularly for inorganic and organic substrates which can be prepared in a suitably transparent form. The transmission technique is based on passing IR energy of intensity I_0 directly through the sample where a portion of the energy is absorbed (Figure 3a). By detecting the remaining transmitted energy as I_T, a transmittance spectrum is obtained. Transmittance spectra are defined by $T = I_T/I_0$, where T is transmittance. Although transmission measurements are very accurate and reproducible for transparent materials, metals and other opaque specimens are troublesome to analyze. Koenig first recognized that transmission spectroscopy could be used to study polymer surface species.[31] By spectral subtraction of a bulk sample spectrum from a surface-treated sample of the same bulk composition, contributions of the bulk phase will be removed and the resultant difference spectrum will represent the IR response of the molecular structure of the surface. The difference spectrum can then be used to measure quantitatively the surface species.[31] For suitable samples, IR transmission measurements are superior to reflection techniques owing to high sensitivity, quantitative measurement, and relative simplicity.

While transmission measurements are commonly employed, poor sample preparation can lead to erroneous results. A typical problem in sample preparation is the adverse effect of surface smoothness, creating interference fringes. This problem can be avoided by mechanical roughening of the surface. Another common problem occurs when samples are too thick or concentrated for accurate FTIR analysis. Since an increase in sample thickness will produce a nonlinear relationship between the IR signal and pathlength, saturation behavior can be corrected by preparing a thinner sample or increasing the proportion of nonabsorbing material.

Figure 3 FTIR techniques: (a) transmission; (b) internal reflectance; (c) reflection–absorption; (d) diffuse reflectance; (e) PA; (f) step-scan.

Table 1 Sampling capabilities of FTIR techniques[12]

Technique	Sampling depth	Sample preparation	Limit of detection	Sample type
Transmission	N/A	Extensive	1×10^{-5} M	Solid, liquid, gas
IRS/ATR	40 Å–3 μm	Minimal		Film, powder, fiber
R–A	Submonolayer–2 μm	Moderate		Reflective substrate
DRIFT	Monolayer–2 μm	Minimal		Powder, fiber
PAS	200 Å–50 μm	Nil	1×10^{-7} M	All
IR microscopy	10 μm cross-section	Extensive		All

DRIFT, diffuse reflectance Fourier transform infrared; R–A, reflection–absorbance; PAS, photoacoustic Fourier transform infrared spectroscopy.

Liquid samples are analyzed with a sealed transparent sampling cell consisting of two windows with a spacer between them to define the pathlength. Several designs are available to accommodate various liquid properties, such as viscous or volatile samples. By increasing the area of the liquid sampling cell and using cell windows of ZnSe or ZnS, analysis throughput can be greatly improved.[32]

When only small amounts of sample are available, microsampling becomes necessary. Microsampling accessories include a broad range of techniques, including transmission and reflectance methods. Microsampling equipment should accommodate the IR beam geometry to ensure that the entire sample is analyzed, while maximizing the sample response. Beam condensers are used to focus the size of the FTIR spectrometer beam to facilitate analysis of microsamples larger than 1 mm. Sample analysis is extended further through the use of FTIR microscopy.

3.3 Internal Reflectance Fourier Transform Infrared Spectroscopy

For samples which are difficult to prepare as transparent films, or if a concentration profile is needed, reflectance techniques are probably more suitable than transmission. Internal reflectance spectroscopy (IRS) can be used to measure optical spectra of a sample in contact with an IR-transparent crystal of higher refractive index, as shown

in Figure 3(b). As light passes through the crystal, a standing wave is formed at the sample–crystal interface. If the sample absorbs a portion of this radiation, the propagating wave will be attenuated. The reflected IR energy (I_R) is ratioed against a background scan to generate the spectra of the sample surface in contact with the crystal. This process is described as attenuated total reflectance (ATR) spectroscopy, which is a contact sampling method used to obtain surface compositional information from polymeric samples.[33,34] In the IRS procedure, as depicted in Figure 4, the IR beam (I_0) is directed at an incident angle (θ) through an IRE of refractive index n_1 on to a sample of refractive index n_2.

The passage of IR light through the IRE depends on the critical angle (θ_c), which is defined as $\sin^{-1}(n_2/n_1)$. Owing to the different refractive indices of the IRE and sample, light reflects inside the crystal when $\theta > \theta_c$ and refracts out of the crystal when $\theta < \theta_c$. The internal reflection element and physical principles of IRS form the basis of numerous configurations from which a variety of sample types can be studied.[22,33]

One of the main advantages of IRS is that it is possible to conduct surface depth-profiling experiments by varying the angle of incidence or using IRE crystals with different refractive indices.[23,33,35] This is expressed by Equation (1):

$$d_p = \frac{\lambda}{2\pi n_1(\sin^2\theta - n_{21}^2)^{1/2}} \quad (1)$$

where d_p (μm) is the distance the evanescent wave extends into the surface and decays to 1/e of the original value, n_{21} is the ratio of the refractive index of the sample to the refractive index of the IRE, and λ (μm) is the wavelength of IR radiation. Typical values for d_p range from 0.2 to 4 μm. Using the surface depth profiling concept, IRS has been applied to analysis of polymer coatings, including melamine polyesters,[36] alkyds,[37] urethanes,[38–41] and latexes.[42–52]

Figure 4 Schematic diagram of the effect of incidence angle on the light path through an IRE (internal reflectance element): (a) $\theta < \theta_c$ refracts; (b) $\theta = \theta_c$; (c) $\theta > \theta_c$ reflects.

Figure 5 Schematic diagram of circular IRE configuration.

The surface sensitivity of IRS has proven to be useful for qualitative and quantitative understanding of polymer substrates.[53,54] For solid polymer films, the most common IRE is rectangular in shape. By applying even pressure to the sample film, intimate contact is made with the IRE and a significant improvement in the S/N of the analysis is seen. A circular crystal was designed for the study of liquid samples which are not readily analyzed with the rectangular IRE. A schematic of the circular cell is shown in Figure 5.

3.4 Reflection–Absorbance Fourier Transform Infrared Spectroscopy

As illustrated in Figure 3(c), R–A is based on the reflection of incident radiation at a specific incidence angle (θ).[55] When the surfaces are highly reflecting, R–A spectroscopy can be used successfully.[56] For optimum intensity of the reflection bands of films 0.5–20 μm thick, angles of incidence between 10 and 60° are used. Films in the nanometer range of thicknesses can best be measured with grazing angle R–A.

In R–A spectroscopy, there are two electromagnetic components present at the surface, the s-polarized component (perpendicular to the plane of incidence) and the p-polarized component (parallel to the plane of incidence). The p-polarized component has an enhanced electromagnetic field at the surface, while the s-polarized component's field approaches zero. For the surface analysis of thin films, only bonds with dipole components normal to the surface can absorb IR radiation. In order not to interfere with the incoming beam, angles of incidence near 80° are typically used.[57] At this angle, very thin films on the surface of a highly reflecting metal surface can be studied in the IR region, making grazing angle R–A spectroscopy a very important technique. Although R–A/FTIR spectroscopy is strongly surface sensitive, more than half of the energy is lost through the reflection optics for a highly reflective sample.

The use of polarized light in IR spectroscopy is an important tool in establishing structure–property relationships in polymer films. Polarization modulation of IR light greatly enhances the sensitivity and characterization capabilities of surfaces and thin films. This is the main premise of the polarization modulation infrared reflection–absorption spectroscopy

(PM/IRRAS) technique.[58] In PM/IRRAS, a photoelastic modulator is used to provide a differentially polarized IR light source which impinges on the sample surface in a near-grazing angle configuration. By employing a lock-in amplifier with a dual-channel input spectrometer, simultaneous collection of the differential polarization and reference signals is made. This technique greatly improves spectral quality, since polarization modulation effectively discerns near-surface absorptions from stray isotropic sample absorptions. Since the sample and reference signals are collected simultaneously, the interfering effect of CO_2 and H_2O absorbances is avoided. Compared with R–A spectroscopy, PM/IRRAS gives a much higher surface sensitivity with added in situ sampling capabilities.[59]

3.5 Diffuse Reflectance Fourier Transform Infrared Spectroscopy

DRIFT spectroscopy differs from other reflective techniques in that the reflectance collected from the sample surface is diffuse, not specular. Samples which strongly scatter and weakly absorb, such as powders or fibers, are ideal for DRIFT analysis.[60] As shown in Figure 3(d), the incident IR light (I_0) is diffusely reflected at all angles with an intensity I_R. Collection optics initially used an integrating sphere to capture the reflected light, but improved cells have been designed for FTIR instrumentation.[61,62]

Diffuse reflectance is defined for samples where the reflected light is isotropic. With a powder sample, both scattering and absorption occur, producing angularly distributed scattered radiation which may be anisotropic. This factor decreases for a larger number of particles such that the reflected light will be diffuse.[63] In order to relate signal to analyte concentration, the Kubelka–Munk theory must be applied. This relates the absorption coefficient (k) and the scattering coefficient (s) by Equation (2):[64–66]

$$f(R_\infty) = \frac{(1 - R_\infty)^2}{2R_\infty} = \frac{k}{s} \qquad (2)$$

where R_∞ is the absolute reflectance of an infinitely thick layer. In practice, the sample response is ratioed to a KBr standard.[62]

For powdered samples, diffuse reflectance is advantageous since the sample morphology remains intact. Specular reflectance remains a limitation of DRIFT, since strong absorptions lead to Reststrahlen bands in the reflectance spectrum, where the bands can appear inverted at their center. This effect makes quantitation of samples with strong absorptivity very difficult.

Figure 6 Diagram of PA cell and related processes.

3.6 Photoacoustic Fourier Transform Infrared Spectroscopy

Unlike reflective techniques, PA spectroscopy is based on the direct detection of the energy absorbed by the sample and does not require contact with an optical element (Figure 3e). As a result, this technique is suited to the analysis of opaque samples of essentially any shape or morphology.[24,67,68] As shown in Figure 6, the PA effect is a result of absorption of modulated IR light, producing corresponding heat fluctuations at the sample surface. The coupling gas phase above the sample surface will undergo subsequent pressure changes, producing a periodic acoustic signal. This acoustic response is measured with a sensitive microphone, and the electrical signal obtained is Fourier transformed, producing the PA spectra.

The basis of PA spectroscopy depends on the two-step process of radiation absorption and thermal diffusion. The amount of IR energy absorbed corresponds to the distribution of IR-active functional groups throughout the specimen. The process of energy conversion to heat is in the nanosecond range, so absorbed energy is released as heat which is transferred to the sample surface. The physics of this process has been mathematically detailed by Rosencwaig, in which the absorbed IR energy is represented by a thermal signal defined by periodic boundary conditions which decreases exponentially as it approaches the surface.[68]

Owing to the dissipative transfer of thermal energy through the solid and gas phases, the concept of thermal diffusion length (μ_{th}) is introduced.[69] Over the distance μ_{th}, the thermal signal is attenuated by e^{-1} of the

initial value, which is also the distance corresponding to 2π/modulation frequency ($2\pi/w$). Therefore, the PA spectra represents the IR functionalities from the surface to a depth of μ_{th} into the solid, with any response below μ_{th} being lost. This relationship is represented as Equation (3):

$$\mu_{th} = \left(\frac{2\alpha}{w}\right)^{1/2} \tag{3}$$

where α is the thermal diffusivity of the sample.[70–72]

Since the intensity of the optical or thermal signal decreases with distance, the photothermal response depends on sample thickness (l), optical absorption length (l_β), and μ_{th}.[69,73,74] These factors allow surface depth profiling experiments, since by altering the modulation frequency, μ_{th} will change, thus providing a different depth of penetration which may range from 0 to 150 μm. PA/FTIR depth profiling experiments are very useful in surface and interfacial polymer analysis,[72,75–77] polymer stratification,[78] time-dependent processes,[79–81] and polymer film formation.[38,39,82,83]

In the last 20 years, PAS has been based on the rapid-scan mode in which the interferometer mirror moves at a continuous and constant velocity to produce a change in retardation. The constantly changing retardation interferometrically modulates the intensity of each wavelength of the IR beam at a specific Fourier modulation frequency, w. By varying the interferometer mirror velocity (V), surface depth profiling is achieved by differences in the modulation frequency of the IR radiation.[72,84] This relationship is shown by Equation (4):

$$w = 2\bar{\nu}V \tag{4}$$

where $\bar{\nu}$ is the spectral wavenumber in cm^{-1}.[85]

One of the drawbacks of the rapid-scan mode is that the depth of penetration is dependent on wavenumber. Hence, low-wavenumber regions provide spectral information from greater depths than the high-wavenumber regions. To eliminate this dependence and obtain a constant penetration depth over the entire spectral range, step-scan photoacoustic (SSPA) FTIR spectroscopy was introduced.

3.7 Step-scan Photoacoustic Fourier Transform Infrared Spectroscopy

Although the majority of PA studies are conducted in the continuous, rapid-scan mode, the use of step-scan analysis overcomes the wavenumber dependence of the depth of penetration. In the step-scan mode (Figure 3f), the interferometer mirror moves incrementally, and the data are acquired at each retardation point, which eliminates the Fourier modulation frequency dependence. As a result, the SSPA/FTIR method allows measurements at constant sampling depths, because a single modulation frequency is applied over the entire spectral range. Furthermore, precise timing of the signal collection and mirror position permits collection of in-phase (I; in-phase with the incoming signal) and in-quadrature (Q; 90° out-of-phase with the incoming signal) components of the PA signal.

Methods of detection in the step-scan mode require a modulated signal to achieve optimal response; therefore, the IR light must be altered by either amplitude modulation (AM) or phase modulation (PM). In AM, the IR beam is chopped to produce a modulated PA signal.[70,86] AM techniques are seldom used, since S/N decreases by 50% as a result of the chopping device, producing a signal with a large dc component. In the PM mode, such as shown in Figure 7, modulation results from dithering the mirror at each retardation during data collection, which modulates the IR beam as a result of constructive and destructive interference.

The major advantages of PM over AM techniques in SSPA/FTIR spectroscopy is a higher source throughput

Figure 7 Schematic diagram of phase-modulation step-scan.

and fewer baseline drift problems since the interferogram is a first derivative in PM. PM step-scan spectroscopy provides a constant modulation frequency for all wavelengths and allows phase-sensitive detection, providing precise control of the probe depth and convenient extraction of the signal phase.[87,88]

Since PA measurements indirectly measure the time lag of the thermal signal to reach the surface, the introduction of phase analysis is useful in determining the depth of absorbing species in the specimen surface. Bertrand applied phase analysis to PA detection by the analysis of sorbed water at the surface of polyethylene (PE).[89] These studies showed that the depth resolution using phase analysis was much higher than could be obtained by changing the modulation frequency. By implementing the phase analysis of the PA signal, the distinction between the surface and bulk signals can be improved by two orders of magnitude. Improvements to the depth profiling resolution of $\leq 1\,\mu m$ are realized from utilizing the PA phase spectra, as shown by Palmer et al.[90,91]

The combination of modulation frequency and phase analysis can be utilized to distinguish multiple layers. Bertrand demonstrated that the optical absorption coefficient, β, of polymeric materials can be measured from phase analysis.[89] Application of basic phase relationships to PA analysis allows the isolation of the surface and bulk signals.

As shown by Poulet et al.,[92] the PA phase (Ψ) for a homogeneous, thermally thick sample can be represented as a function of β and μ_{th} by Equation (5):

$$\Psi = -\pi + \tan^{-1}(\beta\mu_{th} + 1) \tag{5}$$

Since μ_{th} is held constant in the step-scan mode, β can be abstracted.

3.8 Two-dimensional Fourier Transform Infrared Spectroscopy

The advent of two-dimensional (2D) IR correlation spectroscopy extended the application of FTIR spectroscopy into new areas.[27,93,94] In a typical 2D correlation experiment, an external perturbation is applied to the system while changes to the spectroscopic response are recorded as spectral fluctuations.[95] By applying correlation analysis to these signal fluctuations, a 2D plot can be generated which shows spectral features generally not observable in one-dimensional analysis. Using this approach, one can take advantage of the extreme sensitivity of vibrational bands to changes in the local environment of functional groups. As indicated in previous 2D/FTIR studies,[96–100] a wavenumber correlation map allows interpretation of synchronous changes between specific functional groups and improved spectral resolution. An example of a 2D synchronous correlation spectrum is illustrated in Figure 8. This contour plot shows the in-phase changes which occur between functional groups A and B.

Figure 8 2D synchronous correlation spectrum derived from dynamic spectra.

Step-scan 2D/FTIR analysis can be applied to virtually any system in which spectroscopic changes occur as a result of some perturbation applied to the sample. By applying forces, such as pressure or tensile stress, fluctuations in the spectral intensity are induced in the specimen under analysis.

4 POLYMER BLENDS

Polymer blending has proven to be a practical method to improve the macroscopic properties of two otherwise nonideal materials. For example, polypropylene (PP), which has a poor low-temperature impact strength, can be improved by blending with elastomers, such as ethylene–propylene (EPR) copolymers or ethylene–propylene–diene (EPDM) terpolymers.[101,102] By polymer blending, changes are made to the polymer microstructure which ultimately controls macroscopic properties. FTIR has been found to be indispensable to the determination of phase structure in polymer blends, as well as associating intermolecular interactions with spectroscopic changes. These specific topics will be discussed in detail.

4.1 Phase Structure Determination

While polymer blends can be readily studied with such techniques as differential scanning calorimetry (DSC), wide-angle X-ray scattering (WAXS), dynamic mechanical thermal analysis (DMTA), TEM, or SEM, IR

spectroscopy enables us to elucidate structural information in a nondestructive manner at the molecular level. For an incompatible blend, phase separation will take place, leaving the two phases inhomogeneously distributed throughout the sample. The FTIR spectrum of incompatible polymers blends can be represented as the sum of the spectra of the two pure components, while compatible polymer systems can be found as a single phase. In this phase, molecular-level mixing of individual polymer chains takes place from chemical interactions between the two phases. As a result, considerable differences are seen in the IR spectra of polymers in a compatible blend and the pure component spectrum. The molecular-level interaction leads to spectroscopic differences which can easily be shown by subtracting out the pure component contribution, isolating the interaction spectrum. Analysis of a compatible blend was illustrated in the case of blending poly(phenylene oxide) (PPO) and polystyrene (PS). The spectral data were obtained from transmission FTIR of films cast from a chloroform solution on to KBr plates.[103] Substitution of 4-chloro(polystyrene) in place of PS induces the blend to become incompatible, allowing phase separation to be observed. Factor analysis of the FTIR spectra for the incompatible system revealed only homopolymer spectral components, whereas the compatible blend showed additional spectral responses from chemical interactions between the pure components. These additional spectral features can be used to estimate the relative interaction of PPO and PS blended at various ratios or when cured at higher temperatures. From least-squares analysis, the maximum interaction was seen at a 30 : 70 PPO to PS ratio. From these studies, the authors determined that the PPO/PS blend has a lower critical solution temperature of $>200\,^{\circ}C$.

A polymer blend which shows unique properties is poly(vinylidene fluoride) (PVDF) and atactic poly(methyl methacrylate) (PMMA). The exceptional compatibility of these two polymers is attributed to complex formation between polymer chains, even though PVDF is highly crystallizable. Coleman et al. reported on the spectral results and component interactions of blending these polymers.[104] The samples were prepared by dissolving the polymers in acetone and casting on KBr windows for transmission analysis. At 75 : 25 PVDF to PMMA ratio, the blend becomes incompatible, with PVDF forming a crystalline phase. The IR spectra can be closely approximated by adding the pure component spectra at the same weighting ratio. Subsequent analysis of a 39 : 61 PVDF to PMMA blend showed that the IR spectrum can no longer be approximated by the pure component spectra. This is a possible indication of chemical or conformational changes in the system, typical of a compatible blend. From subtraction of spectra of the blended system and pure components, a small residual band at $1718\,cm^{-1}$ was observed, indicating a distinct interaction of the carbonyl groups with a spectral shift of $12\,cm^{-1}$. It was noted that the PVDF spectra show an induced conformational change at a low percentage of PVDF. From these studies, PVDF/PMMA blend compatibility is attributed to chemical interactions between polymer chains of the two components. Another explanation to account for these results is the occurrence of an optical effect.[105,106] Based on the differences between the real parts of the refractive index of the pure components, the blending process can alter the band shapes and cause shifts to lower frequencies. As a comparison, Coleman studied a blend of poly(ε-caprolactone) (PCL) and poly(vinyl chloride) (PVC) in which the refractive indices are identical.[107] In this study, the author correlated frequency shifts and broadening of the carbonyl band to the concentration of PVC, attributing 9% of the carbonyl peak to the frequency shift. As a comparison, an incompatible blend system was studied by substituting poly(β-propiolactone) (PPL) for PCL. This experiment showed no chemical interactions in the IR spectra, confirming that the optical effect does not solely account for the interaction response.[108] A blend of polycarbonate (PC) and PCL was studied with FTIR.[109,110] By increasing the concentration of PC, the PCL crystallinity decreases. This illustrates the plasticizing effect of PCL in a PC matrix and establishes the mobility of PC in the blend.

The processing of a blended system has been shown to influence the distribution of pure components. To determine the effects of processing, Pennington et al. utilized PA depth profiling to identify the distribution of components in injection-molded thermoplastic olefin (TPO).[111] TPO is a rubber-toughened polymer blend of PP, EPR, PE, pigments, fillers, and additives.[112] Because the distribution of TPO components may have significant effects on such properties as adhesion and durability, understanding the distribution of individual components is particularly important. Using various modulation frequencies, talc was detected predominantly at the surface, crystalline PP just below the surface, and the EPR elastomer layer extends into the bulk, as shown in Figure 9. PAS and DMTA analysis indicates that phase separation occurs in the TPO polymer matrix. This phenomena of phase separation of organic coating components has been observed spectroscopically for many systems, including melamine polyesters,[36] alkyds,[37] urethanes,[38,39] and latexes.[51,52]

4.2 Intermolecular Interactions

FTIR theory is used to associate spectroscopic changes with intermolecular interactions, such as hydrogen bonding. Frequency shifts and intensity changes are common

Figure 9 Side profile of proposed stratification profile of TPO.

indicators of the vibrational state of molecular structures. Measurement of these spectroscopic features is useful in determining a molecular origin of thermodynamic parameters.

Characterization of intermolecular interactions has contributed to a better understanding of structure–property relationships in polyurethane chemistry. The exceptional mechanical properties of polyurethanes can be attributed to the interaction of the elastic behavior of the soft segments and the high modulus of the hard segments which phase separate into well-defined regions. In these polymers, IR bands can easily distinguish between the hard segments (isocyanates) and soft segments (polyesters, polyethers or polybutadiene).[113,114] If the proper spectroscopic techniques are used, one may obtain information about the mixing behavior of hard and soft segments through interpretation of spectroscopic features associated with strong intermolecular interactions, such as hydrogen bonding, at the interface between the two components.[115] Previous polyurethane studies examined the effect of mold substrates on molecular interactions at the film–substrate interface.[40] The authors showed that urethane hydrogen-bonded C=O groups exhibit preferential orientation as a function of substrate surface tension. Likewise, substrate surface tension was shown to influence the mobility of additives in latexes[24,116] and film formation of water-borne coatings.[117] Other areas of research rely on surface tension gradients to form self-stratifying coatings.[118,119]

These studies are particularly relevant to polyurethanes because chemical interactions occurring between hydrogen-bonding functional groups will strongly contribute to the mechanical properties of the polymer structure.[120–123] From FTIR spectra, the amide II stretching modes of polyurethane and polyurea are detected at 1535 cm^{-1}. The bands in the 1700 cm^{-1} region, assignable to the amide I C=O stretching vibrations, can be separated into two components. The first, at 1760 cm^{-1}, is assigned to free C=O groups, while the second, at 1690 cm^{-1} is assignable to the C=O groups participating in hydrogen bonding. Since the origins of fundamental vibrations are well understood, both the orientation and relaxation behavior of chain segments can be used to identify the structural component responsible for the toughness of polyurethanes.[115]

PAS is useful in the study of interactions between poly(ethylene terephthalate) (PET) and poly(butylene terephthalate) (PBT).[70] By examination of the crystallization behavior of PET/PBT blends, the kinetic profile was obtained. The crystallization half-life obtained from transmission measurements was in close agreement with the PAS results. PAS analysis, however, did not require extensive sample preparation, unlike transmission FTIR. The SSPA method has been used to examine stratification processes in TPOs by monitoring molecular-level processes that occur near the substrate surface, which inherently influences adhesion to organic coatings.[25] It was shown that the interactions between the substrate components and the coating are strongly influenced by stratification over the sample thickness. Based on rheo-photoacoustic (RPA) FTIR results, correlations between stratification processes and work of adhesion can be determined.

The orientational behavior of blends was studied in a PPO/PS system.[124] It was observed that the PS chains increased orientation with concentrations up to 24% PPO and then remained constant whereas the PPO chains did not exhibit orientational behavior as a function of concentration. These results are explained in terms of the different relaxation behavior of the two types of chains.

5 POLYMER ADHESION

Although macroscopic evaluation of adhesion has important implications, adhesion can be further understood from a molecular-level perspective. Mechanical test methods provide information concerning only the forces that hold two substances together, but do not provide the origin of physicochemical processes responsible for adhesion.[125,126] In contrast, spectroscopic methods are capable of monitoring molecular-level interactions responsible for adhesion and thus further enhance knowledge of the factors promoting or disrupting adhesion.[35,127–129] As FTIR provides a correlation between the spectral changes and interfacial properties at the coating–substrate interface, it has potential for studying the work of adhesion.[130]

Since the characterization techniques previously outlined previously provide information about interactions at interfacial regions, we shall focus on the spectral features that allow measurement of adhesion. By probing interfacial regions, factors which lead to adhesive failure can be identified. This information will allow one

Figure 10 Schematic diagram of adhesion promotion: (a) substrate pretreated with coupling agent; (b) polymeric coating applied to pretreated substrate.

Figure 11 Schematic diagram of adhesion promotion: (a) polymeric coating applied to substrate; (b) interdiffusion of polymeric coating into polymeric substrate.

to modify interfacial chemistry, ultimately leading to the improvement of adhesion. The promotion of adhesion can be achieved by increasing the affinity of the adhesive and adherend. This can be accomplished in many ways: by use of a coupling agent (Figure 10) and through the process of interdiffusion (Figure 11).[131–135]

5.1 Coupling Agents

The adhesive performance of two materials, such as a coating on a substrate, is strongly affected by the nature of the interfacial region. As two homogeneous phases are brought into contact with each other, the presence of incompatibilities at the adjoining surfaces will prevent or limit adhesive interactions. To improve surface compatibility, a primer can be applied to the substrate before topcoat application. The primer, also known as a coupling agent, is a bifunctional molecule which has one functionality capable of reaction with the substrate and a second functionality suitable for reaction with the coating, thus allowing two surfaces to be ''coupled'' together, as shown in Figure 10. The most commonly used coupling agents include silanes, titanates, zirconates, and other bifunctional molecules.[136,137] Since the investigation of primer chemistry is fairly extensive, the focus of this section will be on spectroscopic research applied to promotion of adhesion on substrate surfaces.

Using characterization techniques described previously, silane coupling agent reactions occurring at the interfacial region can be investigated. By using silanes as a composite primer, Chiang and Koenig[138] demonstrated by FTIR studies that amino-substituted silanes are ineffective as coupling agents for anhydride-cured epoxy composites. They showed that anhydrides, instead of reacting with the epoxide groups, undergo a side reaction with primary amine groups of the coupling agent to form cyclic imides, limiting potential cross-linking at the interphase region. Plueddemann later showed that silane coupling agents with chloropropyl, epoxy, or cationic styryl functionalities were more compatible with anhydride–epoxy composites.[139] To characterize further the thermal reactivity of silanes, Culler et al. studied amino-functional silanes placed on a KBr substrate and exposed to air.[140] Subsequent IRS analysis showed the formation of hydrogencarbonates below 95 °C and imines above 125 °C. Carton studied the anhydride and epoxy reaction on Ge at 150 °C for 3 h in the presence of aminosilane using IRS.[141,142] These studies showed that, while water remained at the interface, the silane amino groups were able to react with the anhydride to form amide groups, without the cyclic imide side reactions. Likewise, the conversion of γ-aminopropyltriethoxysilane (γAPS) amino groups into amides was observed on KRS-5 and sapphire crystals to depend on temperature.[143] Subsequent FTIR analysis by Chiang et al. determined that γAPS hydrolyzes almost immediately in aqueous solutions to form stable zwitterion structures.[144]

The prediction of primer thickness and stability is imperative to forming a suitable interphase. As a silane coupling agent is applied to a glass surface, Koenig showed several distinct molecular-level structures are formed.[145] The mechanism of coupling was shown to occur by hydrolyzed silanes hydrogen bonding with silanol groups on the glass surface, forming monolayers up to 300 monolayer equivalents. Using FTIR, the vinyltriethoxysilane adsorbed layer on glass was shown to increase with increasing silane concentration and treatment time.[146,147] Similar spectroscopic studies of γAPS showed much faster adsorption, owing to the autocatalytic effect of the amino group.[148]

5.2 Composite Interfaces

In composites, interfaces between fibers and a polymer matrix are essential in achieving mechanical integrity. FTIR analysis provides an excellent alternative, since measurements can be made without actual contact to the sample surface, allowing studies of fibers and also other nonuniform sample shapes. Urban and Koenig showed that the orientation of surface species could be determined by comparison of PA spectra, one collected with a highly polarizable coupling gas and another with a nonpolarizable coupling gas.[149] Chatzi et al. applied this method to the analysis of Kevlar fibers and showed that orientation of phenyl groups was parallel to the surface of the fiber skin, while the radial orientation of the polymer chains in the fiber core was observed from the N–H stretching modes.[84,150] Tidrick and Koenig investigated the effects of epichlorohydrin and sodium hydride modification on the surface of Kevlar fibers.[151] Improved adhesion of the treated Kevlar fiber in composites was attributed to polyether branching from the polymer backbone, as shown by PA/FTIR spectra. Adhesive improvement was attributed to enhanced compatibility with the composite matrix, without the formation of covalent interfacial bonds.

Nextel™ ceramic fiber/polyimide composite interfaces were investigated using PAS, allowing monitoring of interactions between the fiber and matrix phases.[152] The necessity for a coupling agent was found to depend on the properties of the polyimide. Degradation of Nextel™ fibers in acidic, neutral, and basic aqueous environments was observed using PAS.[153] Using a subtraction method, the presence of positive bands at 1300 and 850 cm^{-1} indicated an increase in borates [$B(OH)_3$] at the surface of the fibers, possibly as a result of B_2O_3 reacting with water. PAS was used to study the effects of oxidation on polyacrylonitrile (PAN)-derived carbon fiber composites with poly(phenylene sulfide) (PPS), poly(ether ketone) (PEK), and epoxy resins.[154] As the degree of oxidation was increased, the band intensities at 2920 cm^{-1} (CH stretch) and 2250 cm^{-1} (CN stretch) decreased, indicating structural changes at the carbon fiber–matrix interface. Studies of the mode and mechanisms of thermal oxidation in glass–nylon 66 composites was also observed with PAS.[155] Thermal oxidation of the composite exposed to 150 °C for 5000 h resulted in transamination reactions and formation of α,β-unsaturated carbonyl species with chain scission.

5.3 Polymer–Polymer Interdiffusion and Adsorption

Adhesion typically takes place in the form of chemical bonding, such as covalent or van der Waals interactions, yet physical bonding plays an important role in the adhesive bonding strength. Physical bonding may result from diffusion of adhesive molecules across the interface to achieve close contact with the substrate or by the forces of physical adsorption between the adhesive and substrate.

Diffusion at polymer–polymer interfaces, such as shown in Figure 11, is important to the adhesive integrity of the bonded system. Voyutskii first suggested that adhesion results from the interdiffusion of polymer segments across the interface.[156] IR spectroscopy plays an important role in the study of interdiffusion, since deuterium labeling of each phase is not required and the diffusion process can be measured in situ.[157] The interdiffusion of a PS–poly(vinyl methyl ether) (PVME) composite was used as a model of adhesion at the interfaces of the two domains.[158] Measurements of interdiffusion of PS/PVME on a Ge IRE at temperatures above and below the T_g of PS allowed the determination of the interdiffusion coefficient (1.1×10^{-12} cm^2 s^{-1}). It was found that interdiffusion is not dominated by either component; instead, it is controlled by the rate of the PVME swelling of PS. Since the extent of adhesion is directly related to the extent of diffusion and the interfacial thickness, this analysis can be applicable to the design of rubber-toughened plastics or bioadhesives.

Adsorption is a phenomenon associated with the exudation or removal of species at an interface. This process is usually governed by van der Waals forces or donor–acceptor interactions. In general, the greater the polarity of two molecules, the greater is the molecular attraction between them. Cook et al. studied the absorption of iron oxide particles to various polymer substrates using PAS.[159] Using subtraction of the iron oxide bands from the spectra, preferential adsorption to more polar substrates, such as a phenoxy (PKKH®), was observed. Similar PA studies were performed to study the adsorption of γ-iron oxide powders on polyurethanes for possible application as magnetic recording media.[160] Surface reactions were apparent on the polyurethane substrates as a result of preferential absorbance to polar functionalities. Characterization of the reactivity of polycyclic aromatic hydrocarbons (PAH) on silica and alumina surfaces was researched by Saucy et al.[161] Folkers et al. illustrated the extensive control over surface wettabilities through the use of self-assembled monolayers (SAMs) of alkanethiol on gold surfaces.[162] By competitive adsorption between short- and long-chain alkanethiols, the structure ordering can be properly established with polarized IR external reflectance spectroscopy.[163] From these analyses, the interfacial region was discovered to be significantly disordered as a result of the relationship between the molecular structure and wetting.

5.4 Film Formation

During the cure of an adhesive, shrinkage usually occurs as a result of cross-linking, solvent loss, or cooling of

the adhesive material. Since the contact area of the adhesive to the substrate remains essentially constant, internal stresses will build up, which ultimately reduce the fracture strength of the adhesive bonding. Greenblatt et al. observed spectroscopically the cohesive failure of polyimide coatings on metal substrates in the presence of the γAPS.[164] The failure was attributed to increased internal stresses due to the thermal mismatch between polymer and metal layers, leading to chain scission of the polyimide. By reducing the imidization temperature from 350 to 320 °C, the adhesive bond strength was shown to increase. In contrast, copper substrates inhibit imidization by the formation of copper carboxylate. In this instance, IRS studies show chemical bonding between copper and polyimide.[165]

An understanding of the chemistry during the film formation process is an invaluable tool in the design of durable coatings. The research of Jang and Lee indicated that the interfacial adhesion between benzophenone tetracarboxylic dianhydride and oxydianiline (BTDA and ODA) polyimide and aluminum depends highly on the imidization temperature.[166] As observed with IRS, increase of the cure temperature leads to the formation of ester and carboxylic groups, at the expense of imide ring cleavage. Shifting of the carboxylic acid band from 1725 to 1710 cm^{-1}, and a decrease from 1670 to 1660 cm^{-1} for the carbonyl group, indicate chemical interaction with the surface hydroxyl groups. The band intensities of these chemical interaction increase with increase in temperature, correlating with a maximum peel strength at 320 °C. Likewise, Flament et al. studied the PMDA/ODA polyimide–aluminum interface (PMDA = pyromellitic dianhydride) using XPS analysis and verified that direct bonding does occur.[167]

The use of vibrational spectroscopy to correlate interfacial forces with work of adhesion has long been a goal of scientists. This approach takes advantage of one of the major strengths of vibrational spectroscopy, namely the extreme sensitivity of vibrational spectra to the changes in the local environment. To accomplish this, a unique method of monitoring adhesion of a coating to a substrate was developed by combining tensile elongation and PA detection as a RPA/FTIR cell (Figure 12).[129,130] With this device, one is able to monitor molecular changes upon applying stress to the substrate. Using this technique, the adhesion of a polydimethylsiloxane (PDMS) coating to a PE substrate was investigated.[168] These studies showed that the intensity of the PE C–H stretching bands at 2925 and 2850 cm^{-1} as a result of elongation of the substrate increases. Although the initial increases are small, possibly owing to thinning of the substrate, a large increase at 17% elongation is attributed to interfacial failure in the form of microvoids. The microvoid formation was independently confirmed by SEM analysis.

6 POLYMER SURFACE CHARACTERIZATION

Many polymers are unsuitable for bonding to other materials because of the low surface energy of the surface structure. The pretreatment of surfaces is a commonly used method to tailor the surface chemistry of polymers and achieve adequate bond strength. FTIR studies have often been employed in characterizing these surface changes, since the region of interest is typically less than 2 μm from the surface. Transmission FTIR has shown limited success in this area owing to the relatively ineffective surface sensitivity of this method. Reflectance techniques, on the other hand, have been used extensively, since these techniques employ nondestructive depth-profiling measurement with preferred sensitivity to surfaces. In the following sections, FTIR studies of surface pretreatments will be presented.

6.1 Plasma Methods

Plasma treatment of polymers consists of placing a material in a vacuum chamber and introducing an appropriate gas which is ionized to form a plasma. During the plasma treatment, adsorbed material on the polymer surface is removed and reactive groups are created through a free-radical formation process. Determination of the changes which take place during this process provides important information for subsequent coating operations.

Plasma pretreatment of polymers has shown promising application in the automotive, medical, and microelectronics fields. The elastomeric nature and relatively inert composition of polymers make this material suitable for biomedical substrates. Plasma polymerization methods have been the focus of recent studies in achieving surface modifications. These modifications are accomplished through the deposition of a thin film or by reaction with surface functionalities. Plasma polymerization provides a well-controlled process for the application of films ranging from 10 to 500 Å using a wide range of monomers. A complete overview of plasma polymerization reactions and characterization of these systems was provided by Yasuda.[169]

Plasma polymerization can be used to obtain uniform polymer coatings on a variety of surfaces. Gaboury and Urban examined the effect of both a nitrogen and argon gas plasma on PDMS films, monitoring surface changes with FTIR/IRS.[170] After plasma exposure, FTIR detected bands at 2158 and 912 cm^{-1}, indicating the formation of Si–H groups on the polymer surface. Waldman et al. used FTIR to characterize polymer deposition rates for controlled adhesion of graphite fibers to PEEK® (polyether-ether-ketone).[171] By monitoring processing parameters, such as composition of the monomer mix, flow rate, pressure, and power of the rf field, the plasma deposition rate was found to be the smallest for 100% ethylene and increased threefold when ammonia was added to the monomer mixture. From the FTIR results, the polymer coatings were found to be of uniform thickness and exhibited a complex cross-linked structure.

In a similar study, hydroxyl-rich surfaces were obtained from a plasma of allyl alcohol on various polyolefin substrates.[172] R–A spectroscopy was used to obtain structural information of the plasma polymerized layers, which were found to be less than 50 nm thick. FTIR analysis verified that the substrate did not seriously affect the chemical structure of the plasma polymer, but the adhesive properties were found to depend significantly on the specific substrate. The difference in adhesive properties between the substrates may be explained as an effect of vacuum ultraviolet (UV) emission present during the plasma deposition. Radicals formed in the plasma near the surface of the substrate cause chain scission reactions, lowering the cohesive strength of the substrate owing to the formation of weak boundary layers. Savage et al. reported an improvement of molecular compositional control by use of a variable duty cycle pulsed rf plasma.[173] The plasma-generated film was monitored spectroscopically using FTIR and XPS. Using SSPA/FTIR, Palmer et al. indicated that, by varying the modulation frequency, depth information of plasma-deposited films of cobalt tetraphenylporphrin and hexamethyldisilazane on PP could be obtained.[71,174]

6.2 Chemical Methods

The surface energy of polymer substrates can be strongly influenced by exposure to specific types of surface treatment. The chemical processes include chromic–sulfuric acid, ozone, and gas-phase fluorination methods. Morphology changes from the chemical treatment of TPO have been observed with PAS.[111,175] FTIR spectra of TPO indicated that stratification of PP crystalline components can be identified by monitoring the bands at 1000 and 843 cm^{-1}. The 1000 cm^{-1} band is attributed to the combination of CH_3 rocking, CH_2 wagging, and CH bending motions, while the 843 cm^{-1} represents the coupled CH_3/CH deformation and CH_2/CH_3 rocking normal vibrations.[176] Previous studies on PP blend properties concentrated on polymer composition,[177] processing conditions,[178] morphology,[179] mechanical response,[180] and paintability. Ryntz showed that changes in morphology of TPO are seen upon treatment of surfaces with solvents.[181] Studies have shown that a relatively small change in cure time or temperature will have a profound effect on film adhesive properties.[182]

Chemical vapor deposition was examined as an alternative technique for preparation of poly(phenylene vinylene) (PPV) films, a promising candidate for the active layer in light-emitting diodes. By depositing a chlorinated xylene layer, polymerization on the substrate surface will give a Cl precursor polymer, which on heating forms the conjugated PPV structure.[183] In situ infrared reflection–absorption spectroscopy (IRRAS), ex situ transmission IR, and polarized IRS spectra were used to characterize these films.

7 POLYMER BULK CHARACTERIZATION

The typical time resolution of FTIR provides spectroscopists with the opportunity to obtain an IR spectrum in the millisecond timescale, enabling the observation of reaction changes to be studied. By plotting the absorbance of a characteristic group frequency, a kinetic profile of the process can be obtained. A kinetic profile can also be obtained by the use of differential spectra by subtraction of each spectrum from the preceding one with respect to time.[184] The rapid sampling provided by FTIR allows the monitoring of short-lived spectroscopic changes for many polymer processes, including curing kinetics,[15,185] orientation,[186] and relaxation.[186] Recent developments in step-scan interferometry pushes the time resolution into the nanosecond range, since the limiting factor is the response time of the detector, not the mirror movement.

7.1 Thermoset Curing

In characterizing polymer curing, it is important to evaluate how both the microstructure and the superstructure change as a function of time. The kinetics of the curing process for polymeric materials can be carried out using FTIR.[15,187,188] By collecting spectra at designated intervals, kinetic profile measurements can be made, where the time intervals of collection are determined by the reaction speed. Accurate study of polymerization kinetics requires rapid collection in a rapid time frame with an extremely fast spectrometer. The relatively new class of spectrometers which are capable of following reaction kinetics have been termed real-time Fourier transform infrared (RTFTIR) spectrometers. Recent advances in FTIR instrumentation have allowed up to 204 spectra per minute to be obtained.[189]

Spectroscopic monitoring of adhesive cure rates is a useful application of IR spectroscopy. RTFTIR was utilized to examine the kinetic profile of an anaerobic adhesive, Loctite® 642.[190] These studies examined the effect of surface-activated polymerization on copper, aluminum, galvanized steel, zinc-plated steel, stainless steel, and passivated stainless steel. The copper surface was the most active surface for initiating the polymerization, while passivated stainless steel specimens showed a higher ultimate degree of conversion and cure speed over the surface without passivation. The increase in surface activity was attributed to the passivation process, which results in roughening and removal of inert oxide layer of the surface. The surface reactivity was evaluated based on the IR spectra of the anaerobic cure in a real-time mode and then correlated with the metal type and content in the interface region. The surface texture and elemental analysis of the metal surfaces were measured using SEM and EDX.

Using RTFTIR, the mechanisms for photochemical reactions of polymer systems can be defined. UV cure reactions typically occur very rapidly, making the spectroscopic monitoring of these reaction difficult. Yang et al.[190] studied the UV-initiated anionic polymerization of ethyl cyanoacrylate. The reaction was monitored using the C=C stretching band at 1617 cm^{-1}. From the RTFTIR data, the highest cure levels were obtained with a high intensity light source with the reaction occurring in the first seconds of the reaction. Other reaction parameters can be studied, such as oxygen inhibition or photoiniator concentration. This information is critical in assessing the structure–property relationships in the adhesive formulation.

FTIR spectroscopy was used to study the photopolymerization of 4,4′-bis(acryloyl)biphenyl (BAB), dispersed in a liquid crystal matrix (E7).[191] The IR absorbance of the carbon–carbon double bond of the acrylate group was monitored to follow the course of the polymerization and to determine the extent of cure. It was observed that a major change in the character of the IR absorbance band shape and position of the acrylate carbonyl group accompanied the decrease in the carbon–carbon double bond absorbance. Curing was found to be rapid, of the order of minutes. It was found that the reaction did not proceed appreciably after a brief initial exposure to UV radiation. This result implies that this type of system may be time-stable with programmable degrees of cure. It was also discovered that single continuous doses of UV exposure produced a higher degree of cure than equivalent UV exposure times administered in multiple shorter doses. This observation indicates the existence of a relatively long induction period in this system. The long induction period may be caused by a UV screening effect due to the other components of this system.

Polyurethanes are high-performance polymers known for abrasion resistance, hardness, and flexibility properties.[192–195] Owing to these factors, polyurethanes are becoming more widely used as coatings. In order to understand the process of polyurethane film formation, FTIR can be used to track cross-linking reactions in polyurethanes[196] and related rheological factors.[197,198] The primary interest is monitoring of the cross-linking reactions when NCO reacts with the active hydrogen of a hydroxy-functional compound and a urethane linkage is formed. A typical polyurethane system is illustrated in Scheme 1. When isocyanate reacts with water by a condensation reaction, an unstable intermediate, carbamic acid, is formed. This immediately dissociates to evolve carbon dioxide gas and an amine, which continues to react with free isocyanate to form urea, as shown in Scheme 2.

Scheme 1

The NCO reaction with water can significantly affect film formation, as the evolution of carbon dioxide gas may result in undesirable property changes. Furthermore, accelerated reaction rates between isocyanates and

Scheme 2

amines may cause a rapid increase in molecular weight and viscosity, thus reducing pot life. Since amines are more nucleophilic than alcohols, urea reactions tend to be faster and may predominate the cross-linking process over the urethane network. Under these circumstances, the presence of water is undesirable and may promote hydrolytic cleavage of polyester groups. Using ATR/FTIR and DMTA, Allison demonstrated the influence of humidity on polyurethane film formation near the film–air and film–substrate interfaces.[199,200] Polyurethane cross-linking reactions have been monitored and quantified by following the decrease of the reactant NCO band intensity along with the increase of the product CO_2 band.[38,40,41] As cross-linking reactions progress, the isocyanate band intensity detected at 2271 cm^{-1} decreases, while the band at 2337 cm^{-1} attributed to CO_2 gas formation increases. The results presented in Figure 13 show Circle™ ATR spectra recorded from 10 to 50 min. These cross-linking reactions leading to polyurethane formation can be quantified by using the Beer–Lambert law (Equation 6):

$$A = \varepsilon bc \tag{6}$$

From the concentration profile shown in Figure 14, the molar absorption coefficient of isocyanate and CO_2 can be determined. During this time, from 10 to 50 min, CO_2 increases much faster than the decrease in NCO.

Figure 13 Circle™ ATR/FTIR spectra of water-borne polyurethane recorded from 10 to 50 min.

Figure 14 Concentration changes of ( ) NCO and (■) CO_2 species as a function of reaction time.

Figure 15 Cross-linking reaction time plotted as a function of RH.

Because NCO functional groups can react with water from the surrounding environment, relative humidity (RH) is expected to have a significant effect on the rate of isocyanate consumption, as illustrated in Figure 15. Because solvent evaporation and partial vapor pressure influence cross-linking reactions, the concentration of NCO was monitored as a function of RH, time, distance from the interface, and polarization. By DMTA analysis of films cured at various humidity levels, the RH influence on glass transition temperature (T_g) and cross-link density (XLD) can be seen. The DMTA results are shown in

Figure 16 (a) T_g and (b) XLD of polyurethane films cross-linked at 20, 40, 60, and 80% RH.

Figure 16(a) and (b) for the polyurethane specimens cross-linked at 20–80% RH.

Component stratification in polymer films has been successfully investigated with ATR/FTIR spectroscopy. Hamada et al. studied the curing process of a polyester and hexamethoxymethylmelamine (HMMM) resin system, in which a concentration gradient was observed.[201] The degree of surface enrichment strongly depended on the HMMM to polyester monomer ratio. IRS analysis indicated that as the monomer ratio was increased above a 29 : 71 HMMM to polyester ratio, an increase in HMMM at the surface resulted. As the monomer ratio was lowered, HMMM became more pronounced in the cured material bulk. The authors explained these results as a selective activation of the curing catalyst at the surface region leading to a gradient in component concentrations. The melamine molecules are able to diffuse and the concentration gradient induces an HMMM current from the inner portions towards the surface. Further studies with butylated resins show very high concentrations of the butylated component on the surface of the film, yet remaining constant in the bulk. Butylated melamine enriched the surface because of the low surface tension compared with that of polyester and solvents in the formulation.

7.2 Film Formation and Stability

As shown previously, the mode and extent of film formation can be monitored readily with FTIR analysis. Hirotsu investigated the protective effects of coatings on polyolefin substrates from oxidative plasma etching using FTIR.[202] PP was coated with an ultrathin polymer layer of hexamethyldisiloxane. After exposure to an O_2 plasma, the IRS results suggested that the cross-linked network of poly(hexamethyldisiloxane) was contributing to an improved etching resistance. FTIR spectra of the PP surface after O_2 plasma treatments indicated an increase in the peak intensity at 1023 cm^{-1}, reflecting Si–O formation. Etching was correlated to the weight loss of the PP substrate after the exposure to an oxidative plasma of O_2 or air. The etching resistance of the protective polymer coating was investigated with respect to the type of polymer, protective layer thickness, and oxidative plasma etching conditions. The weight loss of the coated substrate decreased compared to the uncoated PP film. The etching resistance was attributed to the formation of the cross-linked network in the protective layer.

IRS/FTIR spectroscopy is a common choice for the analysis of interfaces and orientation effects that occur during film formation of water-borne polyurethanes. Previous studies of water-borne systems examined the concentration changes of isocyanate to elucidate factors which influence film formation processes.[41] By examining the amide II stretching modes in the 1530–1560 cm^{-1} region, the influence of RH was correlated with the urethane and urea concentrations near interfacial regions.

Antoon and Koenig studied the reaction mechanism of the copolymerization of cyclic anhydrides and epoxy resins using absorbance difference spectra.[15] Solutions of Epon 828 epoxy resin (Shell), methylbicyclo-[2.2.1]heptene-2,3-dicarboxylic acid anhydride (NMA), and dimethylbenzylamine (BDMA) were analyzed on NaCl plates. The proposed tertiary amine (BDMA) catalysis was not observed, since there were no absorption increases at 1600 or 3500 cm^{-1}, which would indicate changes to C=C or OH groups for the postulated allylic alcohol intermediate. The role of the tertiary amine was observed to differ drastically in the presence or absence of the anhydride functionalities. The preferred reaction mechanism involved activation by the hydroxyl groups in which carboxylamine and hydroxylamine act as active centers during the polymerization. Further kinetic studies of the reaction in the presence of fillers showed that E-glass increased the reaction rates, whereas fumed silica decreased it.

The film formation mechanism of ZrO_2 deposited on a titanium support was followed as a function of the firing temperature.[203] It was found that an intramolecular hydrolysis takes place upon heating, resulting in the liberation of hydrogen chloride. FTIR and Fourier transform Raman investigations revealed that polymorphism occurs in the oxide film. The upper surface of the film is of tetragonal structure, whereas the bulk is a cubic form stabilized by TiO_2 formed by oxidation of the support.

Boerio et al. used the R–A technique to study silanes and epoxy resins on metal surfaces at thicknesses of 15 Å.[204,205] The results indicated that the molecules were absorbed on the reflective surface in a conformation with the oxirane oxygen in contact with the surface.[205]

Characterization of the degradation processes of polymers is essential in establishing the integrity of films. Factors such as temperature, humidity, corrosive elements, acidity, and UV radiation can be integrated into weathering environments for IR analysis. Film degradation studies have been made of thin films of PMMA on gold, nickel, and zinc surfaces using external reflection spectroscopy (ERS).[206] If the optical constants of a film are known, the thickness changes of the film as a result of degradation can be calculated based on reflective theory.[207] The solar-induced degradation of PC on metal surfaces was studied by exposure of the film to a solar source for various time intervals. Increases in absorbance in the 3500–3250, 1690, 1620, 1590, 1490, 1340, and 1260 cm^{-1} regions suggest the formation of hydroxyl, a portion of which is hydrogen-bonded, a salicylate-like carbonyl, and a conversion of carbonate C–O bonds into phenolic C–O bonds.[208] Using an environmental R–A cell, where UV radiation, thermal, and environmental exposure are controlled, the photodegradation of PC on gold mirrors was studied by Webb.[208]

PAS and thermogravimetric analysis (TGA) were used by Paroli et al. to study the effect of UV radiation and aqueous environments on polyurethane sealants.[209] By monitoring the chemical composition, the formulation and filler content were shown to have a substantial effect on the polymer degradation. The most prominent spectroscopic effect was detected by PAS is the 3200–3600 cm^{-1} OH stretching region which results from the cleavage of urethane cross-links.

FTIR spectroscopy is commonly used in assessing the lifetime and degradation pathways of protective coatings under corrosive environmental conditions. The durability of 2-undecylimidazole on a copper substrate was studied by R–A spectroscopy.[210] Since 2-undecylimidazole is commonly used as a corrosion inhibitor, the reactivity with copper was studied at elevated temperatures. From the spectral analysis, cleavage of the imidazole ring was noted in the decomposition products. This information is useful for determination of the integrity of films exposed to corrosive surroundings.

The durability of organosilicon coatings was determined by static SIMS and DRIFT.[211] Hygroscope tests and contact angle measurements prior to spectroscopic surface investigations of a propyl/octylsilane and a methyl/octylsiloxane revealed an improvement in long-term stability with the protective silsesquioxane coatings. Investigations on the weathered coatings after 8 years showed the presence of silsesquioxanes only in case of the propyl/octylsilane system. DRIFT measurements on both fresh and exposed material confirmed the presence of the coating in case of propyl/octylsilane, but not in case of methyl/octylsiloxane.

An IRE cell was used to model the effects of thermal aging in enamel-coated wire.[212] Polyamide–polyimide (SX-81002) was cured on a zinc selenide IRS element coated with a thin film of metallic copper. The coated crystal was inserted in a Circle™ ATR cell housed in a heating jacket and set at 250 °C to simulate thermal aging of enamel-coated wire. Evaluation of the IR spectra in the fingerprint region suggested that the polymer experienced chemical degradation within 23 days of thermal aging. Through comparisons with controls containing copper-free coatings, and aging studies carried out at 28 °C, it was determined that aging at elevated temperatures caused more pronounced chemical changes in the polymer than did exposure to the copper. These results indicate that FTIR/IRS may be a useful tool to detect fatigue after thermal exposure.

The photooxidative stability of acrylic latex films was studied with reflectance FTIR to determine the influence of processing parameters.[213] The nature of impurities and oxidation products generated were characterized and related to photooxidative degradation. IRS and UV spectrophotometric analysis confirmed that hydroperoxides are generated by photochemical process. Initial chemical changes and the subsequent influence on the physical and chemical properties of the acrylic films during the later stages of photooxidation are found to be closely related. The main photooxidation pathways were identified as de-esterification and hydroperoxide formation. While hindered piperidine stabilizers or the addition of a comonomer improved photostability, the incorporation of simple terminal dialkyl acrylamide/methacrylamide groups was shown to reduce photooxidative degradation.

7.3 Orientation Measurements

Recent developments in polymer processing technology have contributed to the development of high-performance materials, by forming fibers or films of ordered polymer chains from their anisotropic states. In these materials, an understanding of polymer chain orientation is important for the evaluation of the material properties of the polymers under study. By employing polarized IR, orientational effects can be characterized by several methods: dichroic ratio,[214] spectral subtraction,[215] sample tilting, or FTIR/IRS.[216]

One of the most interesting recent developments is the use of polarization modulation in the measurement of segmental orientation. The traditional techniques of characterizing molecular orientation include WAXS, small-angle X-ray scattering (SAXS), light scattering,

birefringence and FTIR spectroscopy. Even though orientation information from X-ray scattering can be very accurate and complete, it is still limited to the characterization of crystalline regions. Light-scattering experiments utilize long wavelengths (in the micrometer range), which limits the information obtained to large-scale morphologies. Birefringence techniques are subject to artifacts caused by improper measurements.[217] With improvements in FTIR spectroscopic technology, highly polarized beams can be obtained, making polarized IR absorption experiments a robust tool in orientation measurements. Because of the high selectivity of this spectroscopic method, the orientations of individual structural units can be followed with great accuracy. The usual polarization measurements involve two separate measurements, one parallel and the other perpendicular. From the calculation of their difference, the dichroic ratio is obtained, as well as calculation of the orientation function. For nearly isotropic materials, this type of measurement is limited by the dynamic range of the FTIR instrument. However, with the polarization modulation technique, it is possible to measure the differences directly, thus greatly improving the S/N. This technique was first used with dispersion instruments to measure deformation-induced orientation changes in PE.[218] Structural information is inferred from the relative absorption of intensities of incident IR radiation polarized perpendicular and parallel to the plane of incidence. Polarization techniques are only useful if the bands are previously assigned with well-defined transition moments. Details of polarization experiments and possible errors have been described in a number of studies.[219,220]

Recent improvements in the processing technology of polymers have led to an influx of high-performance materials. In these materials, an understanding of structure–property relationships is critical to the development of new polymers. Garton examined the orientation induced by draw processing of PET fibers.[215] In this case, where uniaxial orientation can be presumed, it is possible to calculate the relative amounts of the trans and gauche isomers. The measurements indicate that increased orientation of the amorphous phase leads to an increase in the trans isomer.

Since developments in spectroscopy allow measurements on the microsecond timescale, Nakano et al. applied step-scan capabilities to time-resolved Fourier transform infrared spectroscopy (TRS) to study reorientational dynamics of liquid crystalline materials.[221] While one-dimensional TRS was used to measure real-time orientation dynamics of nematic liquid crystals under the influence of an external electric field, 2D/TRS showed that the rigid and flexible segments of the liquid-crystalline molecules exhibit different reorientational responses to the applied electric field.

The molecular orientation of surface species at the interfacial region plays an important role in determining the interaction of a coating with the interfacial layers. The interaction of mercaptoester coupling agents with gold surfaces was studied using polarized R–A/FTIR at a grazing angle incident angle.[222] Formation of strong chemical bonding is observed as the thioester bonds to the gold surface through sulfur–metal bonds. Only C_{12} (dodecyl thioglycolate) and C_{18} (stearyl thioglycolate) functional coupling agents self-assemble and form a close packed structure on the surface. The C_{12} alkyl chains of dodecyl thioglycolate are densely packed and oriented perpendicular to the substrate surface. In stearyl thioglycolate, the C_{18} alkyl tail chains are also closely packed and oriented, but the chains tilt from the normal surface, whereas the carbonyl group of the C_{18} thioester is parallel to the surface. For short-chain mercaptoesters, such as octyl thioglycolate, the alkyl chains do not self-assemble or orient on the gold surface. Further studies showed that the interfacial shear strength to steel surfaces is enhanced by mercaptoester coupling agents.

ACKNOWLEDGMENTS

I acknowledge my colleagues (Claudia Allison, Anneke Kaminski, Bor-Jiunn Niu, Heung-Soo Kim, Joe Stegge) for their contributions to this article. I also express my gratitude to Read-Rite Corporation management for supporting this effort.

ABBREVIATIONS AND ACRONYMS

AES	Auger Electron Spectroscopy
AM	Amplitude Modulation
ATR	Attenuated Total Reflectance
BAB	4,4′-Bis(Acryloyl)biphenyl
BDMA	Dimethylbenzylamine
BTDA	Benzophenone Tetracarboxylic Dianhydride
DMTA	Dynamic Mechanical Thermal Analysis
DRIFT	Diffuse Reflectance Fourier Transform Infrared
DSC	Differential Scanning Calorimetry
EDX	Energy-dispersive X-ray Analysis
EPDM	Ethylene–Propylene–Diene
EPR	Ethylene–Propylene
ERS	External Reflection Spectroscopy
FTIR	Fourier Transform Infrared
GC/MS	Gas Chromatography/Mass Spectrometry

HMMM	Hexamethoxymethylmelamine
I	In-phase
IR	Infrared
IRE	Internal Reflectance Element
IRRAS	Infrared Reflection–Absorption Spectroscopy
IRS	Internal Reflectance Spectroscopy
NMA	Methylbicyclo-[2.2.1]heptene-2,3-dicarboxylic acid anhydride
ODA	Oxydianiline
PA	Photoacoustic
PAH	Polycyclic Aromatic Hydrocarbons
PAN	Polyacrylonitrile
PAS	Photoacoustic Fourier Transform Infrared Spectroscopy
PBT	Poly(Butylene Terephthalate)
PC	Polycarbonate
PCL	Poly(ε-Caprolactone)
PDMS	Polydimethylsiloxane
PE	Polyethylene
PEEK	Polyether-ether-ketone
PEK	Poly(Ether Ketone)
PET	Poly(Ethylene Terephthalate)
PM	Phase Modulation
PMDA	Pyromellitic Dianhydride
PM/IRRAS	Polarization Modulation Infrared Reflection–Absorption Spectroscopy
PMMA	Poly(Methyl Methacrylate)
PP	Polypropylene
PPL	Poly(β-Propiolactone)
PPO	Poly(Phenylene Oxide)
PPS	Poly(Phenylene Sulfide)
PPV	Poly(Phenylene Vinylene)
PS	Polystyrene
PVC	Poly(Vinyl Chloride)
PVDF	Poly(Vinylidene Fluoride)
PVME	Poly(Vinyl Methyl Ether)
Q	In-quadrature
R–A	Reflection–Absorbance
RH	Relative Humidity
RPA	Rheophotoacoustic
RTFTIR	Real-time Fourier Transform Infrared
SAM	Self-assembled Monolayer
SAXS	Small-angle X-ray Scattering
SEM	Scanning Electron Microscopy
SIMS	Secondary Ion Mass Spectrometry
S/N	Signal-to-noise Ratio
SSPA	Step-scan Photoacoustic
TEM	Transmission Electron Microscopy
TGA	Thermogravimetric Analysis
TPO	Thermoplastic Olefin
TRS	Time-resolved Fourier Transform Infrared Spectroscopy
UHV	Ultrahigh Vacuum
UV	Ultraviolet
WAXS	Wide-angle X-ray Scattering
XLD	Cross-link Density
XPS	X-ray Photoelectron Spectroscopy
2D	Two-dimensional
γAPS	γ-Aminopropyltriethoxysilane

The infrared spectrum of a polymer or rubber is a profile of its absorption characteristics plotted against infrared wavenumber (or frequency). It is generated when infrared radiation interacts with the molecular moieties that constitute the polymer or rubber material. It is a distinctive property (a ''fingerprint'') of the polymer or rubber sample in the form, manner and environment in which it is being examined. It is based on the absorption of infrared radiation at frequencies that match those of the normal modes of vibration within the macromolecule. These absorption features are characteristic of the molecular configuration, sequencing and conformation, and state of order. Absorptions by internal vibrations predominate in the mid-infrared region (ca. 4000–400 cm^{-1}); they involve a few selected atoms in a molecular (functional) grouping, which is a sub-set of those constituting the macromolecule. External vibrations, such as lattice vibrations, which involve segments of macromolecules in crystalline regions, tend to occur at low wavenumbers (<400 cm^{-1}). The intensity of an absorption band is, to a first approximation, proportional to the number density of vibrating species giving rise to that band. The intensity of an absorption band is related to the dipole moment change associated with the molecular vibration; if it is large then the band intensity will be high. Infrared spectroscopy is highly specific. For some quantitative analyses, it can be very precise and sensitive (<0.1%). It is complemented with Raman spectroscopy, for which the selection rules are different and relate band intensity to the change of polarizability occurring during a molecular vibration. Infrared spectroscopy can be used to identify and analyse the molecular structure, composition, order and morphology, both qualitatively and quantitatively, of polymers, copolymers and rubbers and their products. However, for heavily filled and plasticized formulations the spectral interferences may be too high to allow direct or adequate interpretation of a spectrum, and separation of the components will be necessary for unambiguous identifications.

1 INTRODUCTION

Infrared spectroscopy has a long tradition and remains one of the most widely used spectroscopic techniques in the analysis and characterization of polymers and rubbers, and their products. Sampling techniques are available to examine them in their various forms; they cover both macro- and micro-analysis methods for both bulk and surface layer measurements. It is used to both

identify materials and probe the molecular microstructure and morphology of complex macromolecules. There are many reviews and books on the subjects of polymer study and analysis. They cover both vibrational spectroscopy fundamentals through to experimental practice.[1–13]

This article begins with a short discussion on the range of sample forms and properties. This is followed by concise descriptions of sampling techniques. Discussions of qualitative and quantitative analysis and the peculiarities associated with polymer infrared spectra are then followed by more specific applications sections concerned with chemical, physical, morphological, performance and optical property study and characterization. A short consideration is given to industrial process analysis, before the article text closes with an account of the use of Fourier transform infrared (FTIR) microspectroscopy in the analysis of polymers and rubbers. Since its introduction in the 1980s, FTIR microscopy has made major contributions to advancing the analysis and study of macromolecules. This article does not consider near-infrared analysis (NIRA), since these are covered in article **Near-infrared Spectroscopy of Polymers and Rubbers** in this Encyclopedia, nor does it discuss Raman analyses of polymers and rubbers.

The application references incorporated within this article are not exhaustive, but selected to exemplify a diversity of analyses, studies and polymer types; reference lists within these publications will lead those with particular interests to more comprehensive information.

2 SAMPLE TYPES

As produced, commercial polymers may, for example, be entirely aliphatic or aromatic, or contain both entities. They extend from high through to low molecular weight grades and can be in the form of powders, granules, waxes, dispersions or lattices. Solid forms may be tacky or rigid, ductile or brittle; they may be low-melting (as with some hot-melt adhesives, such as some ethylene/vinyl acetate (EVA) copolymers) or melt at temperatures in excess of 300 °C (such as poly(aryl ether ether ketone), (PEEK), an engineering thermoplastic). A polymer may have different polymorphic or stereoregular forms; some polymers may be amorphous, others semi-crystalline or crystalline. Copolymers may be sequenced in differing ways. Polymer end group balances and functionality may differ throughout a commercial grade range or between manufacturers. The polymer or rubber sample may have been processed into a fiber, film or foam, or molded into an article such as a bottle. It may have been formulated or filled with a range of additives, to improve processability, stability, impact strength, or aesthetic appearance. It may have been derived from a thermoset formulation, or be cross-linked. It may be in the form of a composite with inorganic fibers, such as glass or carbon. It may be part of a laminated structure or a surface coating.

A wide and diverse range of sample preparation procedures and sampling techniques with supporting accessories are therefore available, which enable polymers, polymer composites and rubbers, and their formulated and fabricated products, in their many forms, uses and applications, to be analysed and investigated by using infrared spectroscopy.

3 SAMPLING TECHNIQUES

The infrared spectroscopic analysis of organic polymer and rubber samples is concerned firstly with handling, preparing and presenting materials of many different forms and with many different physical properties in an appropriate way for spectroscopic examination. The infrared spectrum recorded is then used for characterizing their chemical structure or measuring their composition, sometimes investigating their morphology, occasionally determining their optical properties.

Since the majority of experiments are concerned in some way with the absorption characteristics of a polymer or rubber, almost the whole gamut of infrared spectroscopy condensed phase sampling techniques are used to record infrared spectra of polymers and rubbers for analytical purposes. The choice of sample presentation method will depend on whether the measurement is to be made directly from a bulk sample, or from a formulated product, or from a fabricated end-use article, or from material which has been coated onto a substrate. Some approaches will be peculiar to kinetic studies and process investigations. The choice of method will likely not only depend on the physical nature of the substance, but also be governed by the output requirement of the measurement; see section 4 following. The fine detail of a polymer spectrum may well reflect the method of sample preparation.

3.1 Transmission

The optimum (or standard) macro-sample method for a high spectral contrast, high sensitivity, ambient temperature, full range mid-infrared spectrum of a bulk polymer for qualitative and many quantitative or semi-quantitative purposes is a transmission spectrum recorded from a thin, continuous, homogeneous, uniform (interference-fringe free) thickness film. The optimal thickness of the film will depend on the polymer and measurement purpose. To observe the positions of all the peak maxima

in the infrared spectrum of a strongly infrared absorbing polymer, such as a polysiloxane, perfluoro-polymer or a polyaromatic, it is necessary to prepare a film of a thickness of much less than 10 μm. A thin film will also be required to observe precisely the positions of the νCH bands (near 2900 cm^{-1}) for an aliphatic hydrocarbon polymer. However, such a spectrum will probably only be useful for generic fingerprinting. Better qualitative classification will likely be achieved for these aliphatic materials from spectra recorded from film specimens 0.1–0.2 mm thickness, to increase the intensity of the weaker fingerprint bands. Optimal thickness specimens for quantitative purposes will depend on the absorption coefficients of the analyte band(s) to be measured. They may vary from 10 μm or less to several millimeters or more (if a weak or overtone band is used, or the band is characteristic of a low concentration species). In all cases, the film's surfaces must be of a size that is sufficient to completely cover the cross-section of the infrared beam focus in the spectrometer sample compartment (or wherever the sample is placed). If it is smaller, then it must be mounted in a holder that will exclude radiation that has not passed through the specimen reaching the detector, since stray light will cause spectral contrast to deteriorate significantly and have disastrous consequences for quantitative determinations.

3.1.1 Hot Pressed or Melt Cast Film

Thin films from some low-melting, thermally stable polymers may be prepared as a sandwich between two hard infrared transparent windows. For example, a few milligrams of the sample is placed centrally between a pair of appropriately sized polished KBr plates; the assembly is then heated gently until the polymer sample softens or just melts. This may be accomplished on a gradient temperature hot-plate (e.g. Kofler heated bar) or under a heating lamp. When softened or molten the polymer is made to flow evenly into a thin uniform thickness film between the plates by applying gentle pressure on to the top surface of the uppermost KBr window. A safe practice must be instigated to achieve this in order to avoid burning one's fingers; use of a cork to apply the pressure has been recommended.[12] The assembly is then allowed to cool gradually to room temperature, during which time the film sample preparation solidifies. This procedure can be particularly suitable for amorphous materials such as waxes, tarry solids and hot-melt adhesives. Since essentially only hand pressure is applied, rubbery materials prepared in this way may have a tendency to retract on solidification; to prevent this the assembly may therefore need to be clamped at the edges.

For higher-melting polymers, particularly thermoplastics, hot compression molding is a very convenient and effective means of preparing a free-standing film appropriate to an infrared transmission examination, which can be especially well-suited for quantitative analysis, although experience has shown that large surface area film samples with a thickness of 10 μm or less will likely be difficult to achieve routinely by this method.

Various examples of press apparatus are available commercially for hot, compression molding of polymers and rubbers.[14–16] These include small ''constant thickness'' film-making kits, which incorporate water-cooled, heated and temperature controlled platens, for use with a manually operated, hydraulic press, such as that used for preparing alkali halide disks. Larger, hand-pumped, laboratory hydraulic presses are, for example, capable of applying loads of up to 20 tons (~20 000 kg) on a ram of 4 inches (10.16 cm) diameter, operating on square 8-inch (20-cm) platens. These platens may be electrically heated to temperatures in excess of 350 °C; they may be cooled rapidly with water, which flows through them; additionally, some presses allow for programmable heating and cooling cycles, to facilitate the preparation of film specimens with specific thermal histories. In these larger presses, film specimens may be prepared by pressing samples between metal plates (press-plates) of a few millimeters thickness and of the same dimensions as the press platens.

Uniform thickness polymer films with smooth, shiny surfaces on both sides, particularly thinner ones (<0.2 mm) will likely give rise to a transmission spectrum that exhibits interference (channel) fringes. That is, superimposed on the polymer's infrared absorption spectrum will be a sinusoidal wave, which will be most evident in regions of low absorbance. This will act to the detriment of interpretative observations and almost certainly negate high precision quantitative measurements. These interference fringe contributions may, in some circumstances, be minimized or eliminated by gentle rubbing of the polymer film surfaces with wire wool or sandpaper. Press-plates for use with the larger laboratory presses may be cut, for example, from polished stainless steel sheets. Where these are intended for preparing polymer film specimens, then their surfaces may be pre-conditioned in such a way as to induce into the film's surface a finish which nullifies the conditions for interference fringe production. This can be achieved, for example, by grit-blasting (20–30 mesh) the sample contact surfaces of the press-plates, which are then spray over-coated with a very thin layer of a poly(tetrafluoroethylene) (PTFE). The surface roughness introduced is then generally sufficient to negate interference fringe pattern occurrence, but without detracting from uniformity of film thickness. The PTFE coating, which acts as a mold-release agent, *must not* be applied if it is intended to heat the press-plates to temperatures much in excess of 300 °C, since the

decomposition products of PTFE are toxic, some of them highly so. Films from thermoplastics, which melt near to or above 300 °C, can be prepared as a sandwich between aluminum foil, which can be peeled or dissolved away (in NaOH solution) to reveal the polymer film. Film specimens from rubbery and brittle samples may be prepared and subsequently examined as a sandwich between thin sheets of AgCl.

Control of sample thickness during molding may be achieved in one of several ways. Thick specimens (> ca. 1 mm) are most likely best prepared using mold templates, appropriately sandwiched between the press-plates. Thinner films may be molded from polymer material sandwiched between the coated surface of the press-plates. Feeler gauges may be inserted beside the polymer specimen to help define film thickness. In all cases, final film thickness will be dependent to varying extents not only on press temperature, compression pressure and spacer thickness, but also on the amount of material sandwiched between the press-plates. Although perhaps not always possible for exploratory type research samples, samples should ideally be dry and essentially free from monomer, catalyst and solvent residues, otherwise hydrolysis or additional reaction may take place, or bubbles may form in the prepared film. The optimum temperature, pressure and time at which to compression mold a film from a particular polymer will need to be found empirically,[15] although the temperature will likely be close to its melting point. Too high a temperature or for too long may lead to thermal degradation and consequent discoloration, or give rise to bubbles in the specimen; too low a temperature or insufficient pressure may give rise to a sample that has not coalesced fully. Controlled heating and cooling rates may be used to induce certain morphologies into the prepared compression molded film, e.g. a rapid quench (into ice) from the melt will likely "freeze" the specimen in an amorphous state, whereas slow cooling (annealing) may lead to a more crystalline morphology.[15]

3.1.2 Microtomed Film Sections

In some circumstances, thin sections appropriate to a transmission measurement may be microtomed from samples such as polymer moldings. However, this practice is more usually employed and commonplace in the preparation of specimens for FTIR microscopy, see section 14.1.

3.1.3 Cold Pressed Film

PTFE and many of its copolymer powders will coalesce under pressure at ambient temperature. A translucent PTFE disk may be prepared by pressing neat powder in an alkali halide disk apparatus. Some linear polyethylenes may also compact at room temperature into forms suitable for examination; indeed, finely powdered polyethylene has been used as a substitute for an alkali halide as the matrix material for dispersion-disk type preparations for the far-infrared region. Compression by high pressure, such as that achieved in a diamond anvil cell,[16] usually yields a thin film suitable for producing a high spectral contrast fingerprint spectrum from a very small amount of an unfilled polymer or rubber sample. As with microtoming, this approach is most commonly used in the preparation of specimens for measurements by FTIR microscopy, see section 14.1.

3.1.4 Capillary Layer Films

For liquid polymers and some low molecular weight amorphous polymers or polymer fractions, bubble-free films suitable for infrared examination may be easily prepared as a capillary layer by squeezing a small amount of the sample between a pair of infrared transparent windows.

3.1.5 Solution

The number of good solvents for polymer or rubber samples, which exhibit wide transmission windows in the mid-IR region, is very limited. Consequently, solution sampling is used relatively very little for qualitative analyses. Additionally, working with high solute concentration solutions, many of which will be highly viscous, is often too troublesome for routine applications; thin cells will be difficult to both fill and clean. Furthermore, the solubility of a particular polymer may well depend on its crystallinity or molecular weight. This notwithstanding, solution sampling in thicker pathlength cells can be particularly suitable for some quantitative determinations on polymer and copolymer systems, providing solute–solvent interactions are minimal and do not give rise to band shifts or changes of band shape. It does have the advantage of inherent pathlength normalization for standard concentration solutions, and also that the solute, the polymer, will be in a reproducible state.

3.1.6 Solvent or Dispersion/Latex Cast Film

A thin film from a latex, dispersion or soluble resin may be readily prepared, with practice, by casting onto an infrared transparent support for direct examination. Alternatively, it may be cast onto another substrate, such as a glass microscope slide or thick aluminum foil, from which it may peeled off prior to measuring its characteristic infrared spectrum. Film thickness will be determined by solution concentration, deposition volume and spread. Solvent evaporation should be undertaken in a fume cupboard or other appropriate containment environment,

particularly if it is a toxicological hazard. Volatile solvents may evaporate readily at ambient temperature, and the transmission infrared spectrum of the cast film can be checked periodically to ascertain whether all the solvent has volatilized. The aim is to produce an even thickness, bubble free, nonscattering film and to avoid the formation of rings, i.e. where essentially a resin deposit ring rather than a film remains after the solvent has evaporated. This tendency can be alleviated if, towards the final stages of solvent evaporation, the film is gently evenly spread across its support by, for example, using the side of the deposit end of a capillary pipette. Final traces of solvent may require removal by gentle heating, for example, by placing the cast film on its support under an infrared heating lamp or, alternatively, placing the preparation into a vacuum oven. Complete removal of less volatile solvents from cast films or from films cast from solutions in which the resin is strongly solvated can often be very difficult or time-consuming. Prolonged heating under an infrared heating lamp, on a hot-plate or in a heated vacuum oven will likely be required, which must be carried out with due attention to both safe handling and evolved vapor containment. Also, care must be taken to ensure that no polymer degradation occurs. Some polymers may crystallize as the solvent evaporates, producing films that are highly scattering and not optimal for the examination purpose; others may be brittle and prone to cracking. Films from water solutions may be cast onto a nonhygroscopic window such as AgCl foil.

Films cast onto supports that are not transparent to infrared radiation, such as glass or aluminum, will need to be removed from their substrate. This method has been found to be particularly useful for polyamides (nylons) and linear polyurethanes (PUs). Films from these polymers may be cast from formic acid solutions onto glass microscope slides, which after the solvent has evaporated are well washed with water, dried and then peeled from their glass support prior to infrared examination. Films that adhere strongly to aluminum foil may be released by dissolving away the aluminum in caustic solution. Hummel[12] gives information on solvents and solubility for a wide range of polymers and resins.

Spin-coating and metered spreading are two methods utilized for creating uniform, thin (usually sub-micron thickness) layers on substrates. The former may be used to generate thin coatings on transmission windows or polished metal surfaces for reflection–absorption measurements; the latter is usually used for laying down surface coatings on polymer films, and can be useful for creating standard samples for attenuated total reflectance (ATR) investigations, see section 3.2.1. Polymers that are soluble in a convenient solvent can be spin cast from a 1–2 wt% solution. A sample stub is mounted on a low speed rotor (ca. 100 Hz), and a cleaned 13 mm diameter support is attached to the stub with double-sided adhesive tape. The support may be a suitable infrared transmission window, such as KBr or ZnSe, or a gold-coated disk appropriate to a transflectance measurement. Several drops of the polymer solution are then pipetted onto the support and the rotor is spun for a few seconds. This produces a uniform polymer film (of typically a few microns thickness) on the flat substrate. Metered spreading may be accomplished with a hand or controlled speed and pressure coater. Wired bars (K bar™) deposit wet films 4–500 μm thick onto the film substrate.[17]

3.1.7 Alkali Halide Disk and Mulls

The major requirement for a good dispersion preparation is a finely divided analyte powder, with a particle size below that of the wavelength of the infrared radiation. Ideally the refractive index of the analyte should match or be close to that of the matrix medium. In these circumstances, spectra that are free of anomalous dispersion, have a high contrast, and have a good signal-to-noise ratio may be recorded, with backgrounds which are essentially non-scattering. The most common matrix materials have been liquid paraffin oil (Nujol™) and powdered alkali halide, most often KBr. In mull preparations, a small amount (10–50 mg) of sample is first ground vigorously by using a pestle and mortar, and then mulled (intimately mixed) with a small amount of the oil. This suspension is then placed between the faces of two infrared transparent windows and squeezed to form a bubble-free, uniform, thin layer, which commonly has a translucent appearance. In disk preparations, an intimate mixture is made between an excess of dry, powdered alkali halide with the finely powdered sample. For a 13 mm diameter disk, this will typically be between 300 and 200 mg of KBr and 1 mg of sample. This mixture in a die is then pressed under high pressure, using apparatus that is commonly available from many accessory manufacturers. The KBr, which is transparent to mid-IR radiation, coalesces to form a clear disk containing the suspended, uniformily dispersed sample. The KBr disk pressing is undertaken usually with the die connected to a vacuum system for improved disk clarity.[16]

The requirement for preparing a finely ground sample precludes these presentation methods as being suitable for sampling many polymers and rubbers, because of their mechanical properties. Some brittle resins may respond well to normal grinding procedures, and finely divided powder may be removed from hard samples by rubbing them with a diamond-powder face coated spatula. Sometimes the addition of a small amount of solvent to soak and swell the polymer or rubber sample will facilitate sample preparation, since the swollen gel may break down more readily; the solvent must then be

removed by evaporation. Another alternative, which has been used for softer, rubbery samples, is to use a low temperature (liquid nitrogen) grinding accessory.

In general, nowadays neither the mull nor the alkali halide disk method is commonly used for the infrared analysis of polymer and rubber samples, particularly since the availability of diffuse reflectance and photoacoustic-FTIR (PA-FTIR) sampling techniques, see sections 3.3 and 3.5 respectively.

3.2 Reflection Methods

Reflection methods are appropriate to surface layer and coating characterizations, and they may be called into play as being more convenient when specimen preparation for a transmission experiment proves difficult. The principles underlying each technique have been described in detail in the article **Infrared Reflection–Absorption Spectroscopy** in this Encyclopedia and will only be described briefly here. FTIR microscopy applications are discussed later, in section 14.

3.2.1 Internal Reflection

Infrared internal reflection spectroscopy (IRS) is concerned with recording the spectrum of a sample by placing it in intimate contact with the surface of a higher refractive index element (crystal).[18,19] The IRS element is essentially transparent to infrared radiation, and infrared radiation must pass through the element so as to strike the sample at an angle of incidence that is greater than the critical angle at the IRS element–sample boundary. The internally reflected infrared beam emerging from the IRS element will have been attenuated by the absorption properties of the sample. This will yield a spectrum which resembles that recorded from a transmission measurement, but one in which, by comparison, the relative band intensities are skewed, since effectively an increasing pathlength of sample is probed with increasing wavelength (decreasing wavenumber) of the infrared radiation. This technique is commonly referred to as ATR spectroscopy. The evanescent wave created at the element–sample interface, which decays into the sample, also has a dependency on the critical angle at the boundary and the ratio of the refractive indices of the IRS element and sample. The probe depth is lower for higher angles of incidence, and lower for a greater ratio of IRS refractive index to that of the sample. In typical experimental set-ups, IRS can be described as producing an absorption spectrum which is characteristic of the sample surface in contact with the IRS element over a surface layer depth from a few tenths of a micron at short wavelengths to a few microns at longer wavelengths. Effective path length and thereby spectral intensity is increased through the use of multiple internal reflection (MIR) elements. It must be remembered that, in regions where it absorbs infrared radiation the refractive index of the sample and thus its critical angle has anomalous behaviour. As a consequence, particularly for the more strongly absorbing bands, band shifts and profile distortions may result. These may be minimized by using either or both a higher refractive index IRS element and a greater angle of incidence, both of which will, however, reduce the overall intensity of the recorded spectrum.

Techniques in IRS are used extensively in the polymer, plastics and rubber industries.[5,20,21] They are essential tools in identifying, characterizing and maintaining the quality assurance of surface layers, surface treatments and coatings of solid products such as films, fibers and moldings. In addition, polarized infrared radiation IRS studies may be used to gain information on surface structure anisotropy. Horizontal IRS set-ups particularly enable the ready study of lattices, aqueous dispersions and resin coating solutions, while, cylindrical (rod-like) or similar MIR accessories may be used as the key part of a process or polymerization monitoring probe.

Perhaps the classic use of the IRS technique has been the identification of the outer layers of polymer film laminates, for which the thickness of each outer layer was of the order of 0.5 μm or greater. This remains a major use, and is illustrated in Figure 1. Other applications include polymer weathering or irradiation studies, surface contamination investigations, such as additive bleed, surface coating morphology or cure monitoring, blend stratification observations, and polymer surface molecular orientation correlations with process variables. To record an unhindered fingerprint spectrum of a surface coating by the IRS technique, it will normally require that the coating must be of a thickness of 0.5 μm or greater. It is possible, however, to calibrate quality assurance methods that will monitor a coat weight or thickness to a significantly lower amount, especially if the coating has an absorption band in a region in which the polymer substrate shows no absorption features.

3.2.2 External Reflection

The near normal angle of incidence techniques of specular reflectance and reflection–absorption are used primarily as qualitative approaches for fingerprinting bulk samples. Grazing-angle of incidence reflection–absorption is a more specialized approach that optimizes absorption signal intensity for very thin layers of resins on reflective metal substrates. External reflection measurements made with polarized infrared radiation at the Brewster angle can be useful. At this angle, with parallel polarized radiation, reflectance is zero for films on a reflective substrate, so the recorded spectrum displays essentially only absorption features and there is no overlay of dispersion.

Figure 1 Infrared spectra recorded from a food packaging film. (a) Transmission spectrum of multi-layer film; (b) MIR (KRS5 prism, 60° incidence angle) spectrum of outer surface (barrier layer); (c) MIR (KRS5 prism, 60° incidence angle) spectrum of inner surface (heat-seal layer). The packaging film comprises a PP central layer, with an EVA copolymer heat-seal layer (second surface), and a vinylidene chloride/acrylonitrile/ester terpolymer barrier layer (first surface). The spectrum characteristic of each of the surface layers has been clearly isolated from that of the polypropylene (PP) in the internal reflection spectra.

Claybourn[22] is recommended for an overview of external reflectance principles and applications to polymers.

3.2.2.1 Specular Reflectance A pure specular reflectance spectrum will have the appearance of a dispersion curve; i.e. it will have the appearance of that of the first derivative of an absorption spectrum. From such a spectrum it is possible by subjecting it to a Kramers–Kronig transformation to extract the more analytically useful absorption index spectrum.[23,24] To produce a specular reflectance suitable for this approach, the sample must be homogeneous, have a flat surface and be essentially nonscattering. It should also be of a thickness such that no ray that has entered the sample returns to the detector; i.e. it should be ''optically thick'' so that it is free from both reflection–absorption and interference fringe features. An example is shown in Figure 2. (It should be noted that the weak CH stretching bands near 3000 cm^{-1} in Figure 2 show an inverse behaviour compared with the bands below 2000 cm^{-1}. They are not attributable to the polymer and they most likely arise from low levels of surface contaminant and occurred as a result of a transflectance type measurement. The conditions for pure specular reflectance can sometimes be difficult to achieve for weak bands.)

3.2.2.2 Reflection–Absorption, ''Transflectance'' In this approach, practically the infrared spectrum recorded is collected usually from a ''near'' normal incidence (typically between 10° and 30°) measurement made of a thin polymer, resin or rubber sample that is mounted on a reflective metal substrate. The spectrum is essentially equivalent to that recorded in a transmission experiment from a film of about twice the thickness, but superimposed on which will be a weaker specular reflectance spectrum.

A common application of this measurement technique is spectral fingerprinting of coatings on beverage containers, such as cans. It may also prove useful for qualitatively identifying a film that has been cast onto an appropriate substrate.

3.2.2.3 Grazing Incidence Reflection–Absorption The acronym RAIRS (reflection–absorption infrared spectroscopy) is commonly used to define external RAIRS measurements undertaken with p-polarization (electric vector in the plane of incidence) at high angles of incidence (ca. 80° or greater) on thin layers of materials (in the thickness domain 1000 Å or less) on reflective metal substrates. Associated with this technique is the metal surface selection rule. Under the experimental conditions used there is an intensified electric field normal to the metal surface, but a zero field parallel to the surface. Consequently, molecular vibrations with transition moments perpendicular to the surface will be excited and appear enhanced, while those vibrations with transition moments parallel to the surface will be undetected or give rise to only very weak bands. For reasonably intense infrared absorption bands, chemical information and structural ordering data are accessible for monolayer coverage.

3.3 Diffuse Reflectance

For polymer and rubber samples that are diffusely scattering, the diffuse reflectance infrared Fourier transform (DRIFT) measurement technique can provide a useful minimal or no sample preparation method.[5,25] Although complex[16,26–28] in that practically most DRIFT measurements involve detecting to varying extents Fresnel reflection components, both specular and diffuse, together

Figure 2 Schematic illustrating application of the Kramers–Kronig algorithm. (a) Recorded specular reflectance spectrum from a PEEK molding, 0.6 mm thick. (Reproduced from Chalmers et al.,[336] by kind permission of The Royal Society of Chemistry.)

with that radiation which has interacted more intimately with the sample, the sampling technique can be a very convenient qualitative tool. The diffuse reflectance of analytical interest results from penetration of the infrared radiation into the sample, by for example transmission through a powder particle or particles, and subsequent scatter by the sample matrix. However, in many circumstances reproducible sample presentation is a problem, and quantitative comparisons are often very likely to be only of low precision. Quantitative determinations are usually made from DRIFT spectra displayed using the Kubelka–Munk function,[16,27,28] which relates analyte concentration to the diffuse reflectance characteristics of the sample; it is the analog of the Beer's law for absorbance spectra.

To record a high contrast diffuse reflectance infrared spectrum from a powder, which is much more similar to its transmittance spectrum than its bulk reflectance spectrum, requires usually that it be finely divided. It should have a mean particle diameter of the order of or less than the interrogating wavelengths, i.e. $\leq 10\,\mu m$. Additionally, it is common practice to disperse it uniformly into a finely divided powdered, dry, non-absorbing matrix, such as KCl. A specimen of the mixture is then examined which is of ''infinite depth'', i.e. typically 2–3 mm or greater. The combination of dilution, typically in the ratio of approximately 10 : 1 diluent to analyte, together with using finely divided powders, reduce significantly Fresnel reflectance contributions from the sample. For continuous samples, such as films and fibers, and composites a KBr powder overlayer technique has been promoted to both minimize Fresnel reflection artifacts and enhance the relative contributions of surface layers.[1] For hard, intractable or large objects, a convenient approach is to abrade from the article's surface a fine powder with some silicon carbide or a diamond powder abrasive pad, which are available commercially. A DRIFT spectrum may then be recorded from the abraded powder, either in situ on the abrasive pad or removed and dispersed in dried, powdered KCl.

As an alternative to IRS, DRIFT has been demonstrated to be a very convenient method of recording characteristic spectra directly from a polymer foam,[29] regardless of whether it is rigid, flexible, open- or close-structured, see Figure 3.

3.4 Emission

The emittance, ε, at a particular wavenumber (ν) of a sample at a particular temperature may be defined as $\varepsilon_\nu = E_s|E_{bb}$, where E_s is the radiant energy emitted per unit solid angle by the sample at a particular temperature and E_{bb} is the radiant energy emitted per unit solid angle by a blackbody source at the same temperature. It is dependent on both sample composition and sample

Figure 3 Diffuse reflectance spectra recorded from a range of polymer foams. (a) A polyethylene wallpaper; (b) PP packaging material; (c) phthalate plastcized poly(vinyl chloride) (PVC) from a buoyancy aid; (d) polystyrene packaging foam.

geometry.[30] The infrared emission spectrum of a sample is a plot of its emittance versus wavenumber. Following from Kirchoff's law, for a sample in equilibrium at a given temperature, $\varepsilon_v = a_v$ where, a_v, is the sample absorptance. Therefore, the emission spectrum of a thin unfilled polymer film will be similar to that of its inverted transmission spectrum, and as such may be used to fingerprint the polymer material. It is related to the polymer film's transmission (t) and surface reflectance (r) by $\varepsilon_v = 1 - (t_v + r_v)$, as given by Willis.[31]

A common practice is to record the emission spectrum from a thin polymer film on a reflective metal substrate. In this instance, the spectrum resembles more closely that recorded from a transflectance type measurement and emission spectroscopy may be used successfully to examine semi-quantitatively samples that are amenable to analysis by the reflection–absorption technique. For a thin partially transmitting sample on a totally reflective metal substrate, the emittance expression becomes:[30,32]

$$\varepsilon_v = \frac{(1 - r_v)(1 - t_v^2)}{1 - r_v t_v^2}$$

FTIR experiments for determining the emission spectrum of a thin polymer film must encompass measurements that remove background effects from radiating surfaces other than the sample when a cooled detector is used.[27,33]

Transient infrared emission spectroscopy (TIRES),[34] can be used to acquire analytically useful emission spectra from polymer samples that are optically thick. It largely circumvents the problem of self-absorption by examining a thin, heated surface layer of a moving sample, and is appropriate to on-line process monitoring, see section 13.

3.5 Photoacoustic

A wide range of polymer and rubber sample forms have been successfully fingerprinted by PA-FTIR. These include powder, chip, film, fiber, foam, composite, prepreg, and heavily carbon filled materials, such as a sliver from an automobile tire.

For solid samples, the conventional method of recording a PA-FTIR spectrum is by placing the sample in a cup-like holder inside an acoustically isolated, small-volume sealed chamber, the PA cell.[5,27,35–37] The cell is filled with an infrared transparent gas, which is usually helium. Photoacoustic detection involves direct measurement of the absorption of infrared radiation. Modulated infrared radiation is focused through an infrared transparent window onto the sample in the PA cell. The absorbed radiation is converted to thermal energy within the sample, which propagates to the sample surface and is released to cause pressure fluctuations in the surrounding gas, which generate the acoustic waves within the sample chamber. These modulated waves are detected by a sensitive microphone, located in the cell body, and the signals processed to produce an FTIR spectrum.

The relative intensity of absorption bands in a PA-FTIR spectrum is not solely proportional to their relative absorptivities. The key parameters to be considered are the thickness of the specimen, the optical absorption length (which is the inverse of the absorptivity) and the thermal diffusion length. Generalized theories for differing relationships between these parameters have been developed.[38–40] The thermal diffusion length is related to the sample thermal diffusivity and modulation frequency. If, for a particular band, it is greater than the optical absorption length, then saturation will occur. Two types of PA-FTIR measurements are commonly undertaken. The first involves signal detection undertaken when the FTIR is operating in its more conventional rapid-scan mode. For a Michelson interferometer operating in this mode, the modulation frequency (f) is both wavenumber (ν) and scan velocity (V) dependent, being related by $f = 2V\nu$, so increasing the spectrometer mirror scan speed will reduce the sampling depth, although this will still be wavenumber dependent, increasing with decreasing wavenumber. For a constant modulation frequency, which is independent of wavenumber, then the interferometer has to be operated in step-scan mode,[16,41,42] which when coupled with phase modulation can enable the extraction of characteristic information from both surface and submerged layers within a multi-layered sample.[41–45]

4 SAMPLE PRESENTATION

The quality, spectral contrast and quantitative precision of an infrared spectrum recorded from a polymer or rubber sample will likely be very dependent on the choice of either or both the sample preparation method and sampling technique. The choices will therefore likely not be solely governed by considerations such as sample form and measurement convenience but most importantly on the purpose of the analytical study. The requirements for generic typing may not need to be as stringent as for those for spectral matching against a computerized database, which may be less than those necessary for a compositional assurance analysis. Certain investigations, such as those associated with product morphology, will require that the integrity of material physical properties be maintained throughout the measurement, so specimen preparative methods such as dissolution, melting or grinding will not be viable.

5 QUALITATIVE ANALYSIS

The qualitative evaluation of the infrared spectrum of a polymer or copolymer may proceed on several levels. These depend on the intent of the analysis. The most simplistic approach, and the one perhaps most commonly practiced in industry, is that of generic identification followed by empirical or computerized pattern matching. Here, the polymer or copolymer is considered as a collection of functional groups or sub-structural units, for which the observed absorption bands are assigned using well established group frequency correlation tables.[46–48] This will likely type a polymer as, for example, an aliphatic or aromatic or alkyl–aryl hydrocarbon polymer, a polyamide or a polyimide, a polyester or a polycarbonate, a poly(aryl sulphone) or a poly(aryl sulphide). This may then be followed by pattern matching of the recorded spectrum against those in a hard-copy commercial or in-house reference collection, which will yield the next level of detail; for example, differentiating single number nylons, distinguishing PP from polybutene or poly(ethylene terephthalate) (PET) from an orthophthalate resin, or indicating the approximate composition of a copolymer. Alternatively, this end result may be achieved through spectral searching (pattern matching) against a computerized database of reference spectra. Many commercial polymeric materials and their products are formulations, however. Plastics and rubbers may often contain additive recipes with organic components such as antioxidants, UV stabilizers, processing aids, impact modifiers, plasticizers and lubricants. They may contain inorganic fillers for fire retardency or to add mechanical strength. Unless separated, these additives and modifiers may well contribute bands of significant intensity to the recorded spectrum.

The next level of investigation may be considered as correlating specific spectral features with particular

molecular conformations or phases. It might involve attributing certain bands or groups of bands to chemical structure differences associated with, for example, comonomer sequence lengths or modes of monomer insertion (e.g. 1,2- or 1,4-polybutadiene), end groups or, in the case of a thermoset, degree of cure. In any detailed interpretation of the infrared spectrum of a polymer one must take into account both the chemical and physical state of order of the system, see section 7.

Further interpretation of a polymer's absorption spectrum may then proceed by measuring the response of individual bands to polarized radiation. This aids both the assignments of bands to their symmetry species and in distinguishing possible chain structures. Much more complex, and a task infrequently undertaken by many practicing analytical infrared spectroscopists, is band prediction and assignment by a normal coordinate analysis (NCA).[3–6,8,9,49] The number of normal modes may be calculated from symmetry and group theory considerations. Iterative procedures based on force fields, derived from knowledge of bond distance and angles, are then used to predict the vibrational modes.

6 QUANTITATIVE ANALYSIS

To a first approximation, the absorption of an infrared band is linearly proportional to the number density of species giving rise to that band. As a consequence, infrared spectroscopy is a very valuable, cost-effective and widely used tool for the quantitative analysis of polymers and rubbers.[1,2,7,16] Although measurement procedures need to be calibrated, quantitative applications are diverse. For example, they extend from determining additive and residual monomer levels and copolymer composition, through end-group concentration determinations and cure monitoring, to dynamic and kinetic studies, to conformational analysis and measurements of molecular orientation and packing, to optical property definition. They are applied routinely in support of research, product development, competitive analysis, at-line quality assurance and in-line process measurements. Whatever the purpose, it must be remembered in developing any quantitative method that polymer infrared spectra are sensitive to changes in copolymer sequencing, tacticity, molecular conformation, molecular orientation and configuration.

The basic law, Beer's law, gives the relationship $A = \log_{10} I/I_o = kcx$, where A is the absorbance, I and I_o represent the amount of radiation transmitted and incident upon the sample respectively; c is the concentration of the absorbing species; k is a constant specific to the species and the wavenumber; x is the sample path length/thickness.

For thicker continuous, uniform polymer films (typically 0.1 mm or greater) in transmission, a quantitative method may only require measurement of the absorbance of a single band attributable to the analyte species, this being normalized against sample thickness, which has been determined using, for example, a dial gauge micrometer. The film's average thickness can be calculated by taking and averaging an appropriate series of micrometer readings over the area examined by the infrared beam. Most other univariate methods will be based on a measure of an absorption band ratio. If one of these bands may be considered as an ''internal thickness reference'', that is its absorption intensity is independent, essentially, of changing concentration, then it may be simply used to normalize the absorption intensity of the analyte band. In a two component system, A + B, in which the level of B is in large excess, it may be possible, for example, to consider the concentration of B as being essentially constant. The absorbance of a band due to B will therefore be indicative essentially of sample path length. An absorbance band ratio, A_A/A_B may then be plotted against the property value of A. If both A and B vary significantly, the absorbance ratio A_A/A_B should be plotted versus the property concentration ratio of A/B. A half-bandwidth rather than a peak intensity measurement may be more appropriate for some determinations. For instance, increasing molecular packing (crystallinity) will likely lead to band narrowing.

For more complex analyses, where, for example, extensive band overlap may preclude developing a high precision univariate quantitative method, multicomponent or multivariate analysis procedures may be used. Commonly used amongst these are principal component regression (PCR) and partial least squares (PLS). In addition, these chemometric methods are also frequently used in industry to analyse more simple systems, particularly for process measurements, since they can provide more robust, more precise, faster and convenient procedures for at- and on-line analysis of polymer and rubber properties.

Examples of quantitative applications of infrared spectroscopy in the analysis of polymers and rubbers feature later in this article and in many of the references cited, so consequently will not be illustrated specifically here. Key to many of these will be feature separation or highlighting through linear absorbance subtraction processes; contrast enhancement may be achieved in others through application of band resolution techniques, such as curve-fitting, or spectra enhancement processes, such as derivative spectroscopy or Fourier self-deconvolution (FSD).[1,7,16,50]

7 POLYMER SPECTRA

The infrared spectrum of a polymer can be a complex superimposition of many effects, but as a consequence analytically very valuable and informative. When interpreting the fine detail of the infrared spectrum of a polymer it should borne in mind that a polymer is not a single compound, and many of its qualities will affect its spectrum. Polymers have a molecular weight distribution, and chains have terminal groups which may be chemically significantly different from those in the main chain, and whose concentration will differ with chain length, as may their balance. Chains may also have side branches, which may be of differing lengths. They may be cross-linked. Polymer chains may contain irregularities through, perhaps, different insertions of monomer units, e.g. unsaturated aliphatic monomer units may polymerize via head-to-head or head-to-tail insertion, or through a vinyl group by 1,2- or 1,4- addition, with the latter existing in either a cis or trans conformation. Many polymers at room temperature may exist in equilibrium with as much as a few percent of absorbed water, which has characteristic bands in the infrared spectrum recorded from the polymer. Similarly, particularly for commercial materials, some polymer spectra may exhibit absorption bands that are directly attributable to catalyst or monomer residues. Copolymers may not only be manufactured with varying compositions, but also with differing sequences of the co-monomer units. For example, propylene/ethylene copolymers are sold commercially in many different grades. These may be obtained by varying the monomer feed concentrations. Materials are produced for commercial applications in which the copolymerized ethylene units are all present essentially as isolated units within the copolymer chain. Alternatively, they are also manufactured as grades in which the ethylene units are present mostly as longer (block copolymer) sequences within the copolymer chain, or sometimes with long sequences at the copolymer chain end (end-block). Some grades even contain distributions of each of these. Many solid phase polymer spectra are also particularly sensitive to state of order; they will be characteristic of stereoregularity, molecular conformation and molecular orientation and ordering. Many polymers are supplied commercially as formulated products (composites, plastics), the other constituents of which will likely contribute additional characteristic absorption bands to the infrared spectrum recorded from the bulk material. These additives may include stabilizers and property enhancers, such as antioxidants, UV-stabilizers, slip-agents, impact modifiers, processing aids or fire retardents; or they may be there for aesthetic purposes, such as pigments or dyes; or they may be fillers or reinforcing agents. Plastics may also be constituted as a blend of polymers; thermoset resins may be supplied as unreacted constituents.

7.1 Isomerism, Conformation, Tacticity, Regularity, Configuration and Crystallinity

Since infrared spectra are particularly sensitive to chemical group configuration and conformational isomerism, they play an important role in defining the structure and chemical composition of many polymers and rubbers.[1,4,5,9,11,51] The monomers butadiene and isoprene can, for example, each be incorporated into a growing polymer chain in one of several isomeric forms (see Figures 4 and 5), depending on the synthesis conditions. Stereo-isomeric structures in polybutadienes may be distinguished and in some cases reliable estimations of their composition determined from the γ-vibrations (out-of-plane CH deformation vibrations) of their hydrogen atoms attached to the olefinic bond (see also, polyethylene unsaturation in section 7.3). The 1,2-addition will be characterized by absorption features at 910 cm^{-1} and 990 cm^{-1}; the *trans*-1,4- and *cis*-1,4-polybutadienes

Figure 4 Polybutadiene chain units.

Figure 5 Polyisoprene chain units.

Figure 6 Polymer chain unit.

will give rise to absorption bands at 965 cm^{-1} and 735 cm^{-1} respectively.[2,9,12] *cis*-1,4-Polyisoprene, which occurs naturally in an essentially pure form known as hevea (or natural rubber), and *trans*-1,4-polyisoprene, existing naturally as gutta percha and balata, however, are not readily distinguishable by this vibration, since both show an absorption band near 830 cm^{-1}.[2,5,12] The 1,2-addition polyisoprene stereoisomer has absorption bands in similar positions to its polybutadiene counterpart, while, the 3,4-configured polyisoprene shows a band characteristic of the pendant methylene group near 888 cm^{-1}.

Polymers like 1,2-polybutadiene, PP, PVC, poly(methyl methacrylate) and polystyrene, have the basic structure shown in Figure 6, where $R_2 = H$ for 1,2-polybutadiene, PP, PVC and polystyrene; $R_2 = CH_3$ for poly(methyl methacrylate). R_1 is $CH{=}CH_2$ for 1,2-polybutadiene, $-CH_3$ for PP, $-Cl$ for poly(vinyl chloride), aryl ring for polystyrene, and $C(=O)-O-CH_3$ for poly(methyl methacrylate).

These are examples of polymers that have the possibility of forming stereoregular structures. Successive repeat units may follow each other in a regular configurational sequence. If they have the same configuration they are termed isotactic, if they alternate it is known as a syndiotactic sequence, see Figure 7. Atactic polymers exhibit no overall regularity in the configuration incorporation of successive repeat units when subjected to X-ray diffraction examination, although short-period regularity within polymer chains may still be evident in a nuclear magnetic resonance (NMR) spectrum.[1] They give rise to spectra that are very similar to those of the amorphous polymer.

Many stereoregular polymers that are substantially pure tend to take up preferred conformations. It is common for the backbone atoms of isotactic α-olefin polymers to assume a helical arrangement. An isotactic PP chain will coil into a 3_1 helix, i.e. each turn of the helix involves three repeat units. Polybutene (polybut-1-ene) and poly (4-methyl pent-1-ene) also form isotactic helical structures. PVC favors a planar zig-zag conformation.

Figure 7 Schematic showing *isotactic* and *syndiotactic* chain unit sequences.

Conformationally regular polymer chains may pack together in a regular arrangement to form a three-dimensional crystalline phase, and highly stereoregular polymers tend to be crystalline. While stereoregularity in vinyl polymers is a prerequiste for the formation of crystalline domains, crystallinity *per se* in a polymer does not imply stereoregularity, it only implies conformational regularity, which may also be associated with amorphous regions. Helical isotactic PP is a semicrystalline polymer, as are many polycondensation products, such as PET and PEEK. Syndiotactic PP may be crystallized in either a 4_1 helix or planar zig-zag conformation. For each of these crystalline arrangements of PP chains there is a distinct fingerprint infrared spectrum[52,53] associated largely with the conformational regularity. Distinct bands may also be associated with the trans and cis isomers of PET, but whereas the latter only resides in the amorphous regions, trans sequences may be present in both amorphous and crystalline phases.[54,55] A poly(but-1-ene) film prepared from the melt will likely exist in the Type II crystalline modification, but with time this will revert to the higher density Type I form. This change, from a material with tetragonal 4_1 helix crystalline phases to one with 3_1 helix rhombohedral crystalline domains, may be observed readily over a few days by changes in the fingerprint infrared spectrum. Polytetrafluoroethylene, which also forms helical structures, can be very highly crystalline as manufactured, in the unsintered state. Above 19 °C PTFE has 15 $-CF_2-$ groups in the identity period, and the 15_7 helix unit cell arrangement is hexagonal; below 19 °C PTFE has 13 $-CF_2-$ groups in the repeat period and the 13_6 helical conformation packs in a triclinic structure.[56] Estimating PTFE crystallinity from an ''amorphous'' band at 778 $cm^{-1}$is the basis for a standard method implemented within industry.[57,58] Linear polyethylene can also have a high degree of crystallinity, and the orthorhombic unit cell contains two polymer chains. In the crystalline domains, the planes of the all trans zig-zag chains alternate perpendicular to each other. Vibrations on adjacent chains may then be in-phase or out-of-phase, and intermolecular coupling changes lead to correlation-splitting of certain bands,[6,8,9] notably the CH_2 rocking mode, which can give rise to a characteristic sharp doublet at ca. 730 and 720 cm^{-1}. It should be noted that the picture of a polymer as a two-phase (crystalline/amorphous) mixture is too simplistic for many systems.[9] For example, polyethylene requires three phases at least to describe its morphology. Raman spectroscopy is a valuable complementary technique to these investigations, and can sometimes be a superior tool for elucidating morphological effects.[59] Furthermore, under certain conditions, polyethylene can undergo a morphological change to a monoclinic structure, which features only a single CH_2 rocking mode band near

720 cm^{-1}. The unit cell of crystalline syndiotactic zig-zag PVC traverses two polymer chains, but as manufactured, although having a preponderance of planar syndiotactic sequences, comprises a mixture of other conformational sequences.[4,8,9,60] Resolving and assigning the component νC–Cl vibrations (750–550 cm^{-1}) has been the subject of several extensive investigations.

Although polymorphism is common among polymers that are crystalline, it is usually only one particular tactic form that has commercial significance as a crystalline or semi-crystalline material, e.g. isotactic PP.

The room temperature, solid phase mid-infrared 1300–800 cm^{-1} region spectra of a stereoregular aliphatic polymer usually contains many weak to medium intensity relatively sharp bands, see Figure 8. This pattern of bands is characteristic of essentially a single polymer chain in a preferred conformation and arises from conformational regularity, i.e. the chain spatial geometry, which is a consequence of the stereoregular structure, i.e. the bands are strictly indicative of regularity rather than being true crystallinity bands. In the melt, their spectra resemble closely those of their amorphous or atactic counterparts.

The far-infrared region (<400 cm^{-1}) is more appropriate for direct monitoring of polymer crystallinity, rather than the largely implicit observations associated with the mid-infrared region. Most of the low-frequency vibrations involve intermolecular associations, and are therefore influenced significantly by lattice packing of chains.[61] For example, differences observed in the far-IR spectra of isotactic PPs, particularly at 100 K, reflect the environments of the chains within particular unit cell (α, β, γ and smectic) configurations.[62]

Figure 8 Infrared absorbance spectra of some poly(α-olefins), ca. 0.25 mm thickness. (a) Poly(4-methyl pent-1-ene); (b) polypropylene; (c) poly(but-1-ene).

7.2 Infrared Dichroism and Molecular Orientation

Many polymers are supplied as products in which the polymer chains are oriented (aligned) to some controlled extent during the fabrication process; for example, fibers, films and bottles. This imparts certain desirable end-use physical properties, such as directional stiffness. Polarized infrared spectroscopy is a particularly useful and practicable tool for investigating polymer anisotropy.

In the next two sections, summaries are presented of the principles underlying measurements of molecular orientation by infrared spectroscopy; rigorous derivations and treatments of orientation distribution functions (ODFs) and their measurement may be found in several of the cited references and references quoted therein.

7.2.1 Dichroic Ratio

Absorption of infrared radiation occurs when there is a change of dipole moment during a characteristic vibration of a polymer. Depending on the nature of the vibrations, they may have transition moments (directional changes in dipole moment) parallel, perpendicular or at some other angle to the major symmetry axis of the polymer, i.e. the chain axis. The directional character of the transition moment forms the basis of polarized infrared measurements.[13,63–67]

When investigated by using plane-polarized infrared radiation, the absorbance, A, of a polymer chain group is proportional to the square of the scalar product of the transition dipole moment vector, μ, of the group vibrational mode and the electric vector, E, of the incident polarized radiation. It is therefore also proportional to the square cosine of the angle, θ_μ, between the transition moment dipole and the electric vector, see Figure 9, $A \propto \vec{\mu}^2 \cdot \vec{E}^2 \propto \cos^2\theta_\mu$.

In general, oriented samples are examined with the infrared radiation beam polarized horizontally or vertically by reference to the axes of the sampling plane in the infrared spectrometer. The sample reference directions to be used may be chosen under crossed polarizers to coincide with the principal optical axes of the refractive index ellipsoid, although for commercial samples these may not always correspond exactly to the geometric axes of the product. For a fiber or uniaxially oriented film the axes of interest correspond to the direction of draw, OX_3, and the direction perpendicular to the draw. For a biaxially oriented film the axes in the film plane are often referred to as the forwards draw (FD) (or machine draw (MD)), OX_3, or sideways draw (SD) (or transverse draw (TD)), OX_1, directions, respectively. For a film sample, OX_2 is normal to the plane of the film, i.e. in the thickness direction. (Biaxially oriented films may be manufactured by either the stenter or a bubble process. For the former, the principal orientation directions will likely lie close to the MD and TD in the film center, but may well be displaced from these at the edges.)

For a drawn system of uniaxial symmetry, the dichroic ratio, R, is measured as:

$$R = \frac{A_\parallel}{A_\perp} \quad \left(\text{or } R = \frac{A_\pi}{A_\sigma}\right.$$

where, $A_\parallel$ and $A_\perp$ represent the absorbances of the investigated band measured with the infrared radiation polarized parallel and perpendicular to the draw direction, respectively. The dichroic ratio may have values from zero to those approaching infinity, depending on the angle β, see Figure 9. If $R > 1$, the mode is said to be a parallel mode (π mode); if $R < 1$ then the mode is said to be a perpendicular mode (σ mode).

For a sample with uniaxial orientation, then $R_o = 2\cot^2\beta$, where R_o is the dichroic ratio of an idealized, perfectly uniaxially oriented sample, for which the transition moment vector makes a cone with a semi-angle β with the local chain axis of the polymer chain (or segment of chain),[13,63] see Figure 9. (Note: if $\beta = 54°44'$, $R = 1$ and the absorption will be independent of the direction of the electric vector of the infrared radiation!)

For a simple, but physically unrealistic, description of a one-way stretched polymer sample with axial symmetry

Figure 9 Schematic showing geometric relationship between sample axes, $OX_1X_2X_3$, the polymer chain axis, x_3, the transition moment dipole, μ, and associated angles for an oriented polymer film sample.

in which f represents the fraction of molecules that are perfectly aligned parallel to the symmetry axis, and $(1-f)$ represents the fraction of polymer chains that are perfectly random:[63,64,68]

$$f = \frac{(R-1)(R_o+2)}{(R+2)(R_o-1)} = \frac{(R-1)(2\cot^2\beta+2)}{(R+2)(2\cot^2\beta-1)}$$
$$= \frac{2}{3\cos^2\beta-1} \quad \frac{(R-1)}{(R+2)}$$

For a mode for which the transition dipole moment is along the chain axis, then $\beta = 0$ and the equation above simplifies to:

$$f = \frac{R-1}{R+2} \equiv \frac{A_\parallel - A_\perp}{A_\parallel + 2A_\perp}$$

For a vibration for which the transition dipole moment is perpendicular to the chain axis, then $\beta = 90°$ and:

$$f = \frac{-2(R-1)}{R+2}$$

In reality, there will be a three-dimensional distribution of chains with different values of θ. f is numerically identical to the Hermans orientation function,[69] which is a function of the average squared cosine of θ:

$$f = \tfrac{1}{2}\langle(3\cos^2\theta_\mu - 1)\rangle$$

The orientation function f describes the average of the quantity and $\langle\cos^2\theta_\mu\rangle$ denotes the average cosine squared value of the angle θ_μ between the reference direction in the sample and the transition dipole moment direction.

7.2.2 Orientation Distribution Functions

The quantity $\langle(3\cos^2\theta_\mu - 1)\rangle$ is the second moment of an ODF (the second-order Legendre polynomial in $\cos\theta_\mu$).[66,67,70,71] $\langle P_2(\cos\theta_\mu)\rangle$ (or P^μ_{200}) may therefore be determined from infrared spectroscopy measurements:

$$P^\mu_{200} = \langle P_2(\cos\theta_\mu)\rangle = \tfrac{1}{2}\langle(3\cos^2\theta_\mu - 1)\rangle$$

The range of values for this expression varies from $-1/2$ to 1. If the dipoles are aligned along the draw direction, $\theta_\mu \to 0$, and $\langle P_2(\cos\theta_\mu)\rangle$ is unity; for perpendicular alignment, then $\langle P_2(\cos\theta_\mu)\rangle$ becomes $-1/2$; for random orientation, $\langle P_2(\cos\theta_\mu)\rangle$ becomes 0.

While the dichroic ratio may be used as a convenience for comparative purposes, P_2 values are generally more analytically useful parameters to determine from the infrared spectrum.[66,67,70] They may be compared with P_2 values obtained from other measurement techniques, such as NMR and birefringence, and correlated more effectively with process variables, such as draw ratio. However, it is important to stress that the P_2 information derived from infrared is very limited.[72] It measures at best an average orientation; it says nothing about the shape of the distribution function. (More informative order parameters may be determined from Raman (P_2 and P_4) or NMR (P_2, P_4 and P_6)).

$\langle P_2(\cos\theta_c)\rangle$ defines the average alignment of a molecular axis or segment of a chain axis rather than that of a dipole moment transition. In practice, particularly for correlating product performance with infrared spectroscopic observations, it is more informative to determine the alignment of a specific molecular axis rather than of a dipole moment. In order to determine P_{200} (uniaxial symmetry about the draw axis) for the chain axis the dichroic ratio, R, must be determined for an absorption band with known dipole moment angle, β, to the chain axis, since β will vary for different bands. The orientation function is related to β and the dichroic ratio by the expression:[66,67,71,72]

$$P_{200} = \langle P_2(\cos\theta_c)\rangle = \frac{1}{P_2(\cos\beta)}\langle P_2(\cos\theta_\mu)\rangle$$
$$= \frac{2}{(3\cos^2\beta - 1)}\frac{(R-1)}{(R+2)} = \frac{1}{2}\langle(3\cos^2\theta_c - 1)\rangle$$

Four P_2 orientation averages that may potentially be determined from polarized IR measurements have been defined for different orientation symmetry cases.[66,67,70]

The objective of most investigations is to characterize the effects of process variables on molecular orientation.[71] Determining the dichroic ratio and then the orientation function for some one-way drawn samples requires simply that the absorbances of appropriate orientation sensitive band(s) be measured with the infrared radiation electric vector parallel and perpendicular to the sample draw axis. For weakly absorbing bands or for thin samples these may be made in transmission. Planar orientation may be characterized similarly for some biaxially drawn (or similar) samples. However, both uniaxial lengthening and biaxial stretching processes may induce molecular orientation anisotropy in the direction normal to the sample surface plane, and measurements in three dimensions are required for determining the orientation functions. In these calculations an important relationship is:

$$A_o = \frac{A_{X_1} + A_{X_2} + A_{X_3}}{3}$$

where A_o represents the absorbance of a band exclusive of contributions due to orientation of the polymer,[65,71] and A_{Xi} is the absorbance along the OX_i axis. It may be used as a normalization parameter to determine comparative measures of orientation in a sample, i.e. A_{X_1}/A_o, A_{X_2}/A_o and A_{X_3}/A_o.

To determine all the average second-order orientation parameters that may be calculated from infrared measurements for oriented samples that have other than uniaxial symmetry about the draw axis, e.g. a biaxially oriented film, then measurements must be made for which there is a component of the electric vector parallel to the normal of the sample surface, which in the case of a polymer film is its thickness direction.[67,70] This has been achieved in a number of ways. Transmission and calculation procedures on tilted thin films have been developed,[13,64–67,70,71,73,74] as have surface layer measurements using IRS approaches.[67,71,75–78] Early developed ATR methods relied on non-standard accessory designs, assumptions regarding refractive index and optical path lengths, and was practically difficult. Many of these limitations may be circumvented if measurements made on dichroic bands are normalized relative to a non-dichroic internal band in the sample spectrum.[79] A similar normalization approach has been used successfully for external (specular) reflectance measurements.[80,81] Providing specimen preparation does not induce or alter the orientation characteristics, an alternative approach is to microtome thin orthogonal sections through a sample and examine each by transmission FTIR microscopy.[82,83]

The average cosine squared values for the angles between the sample and polymer chain axes systems are another set of useful and frequently determined descriptive parameters.[67,72] For example, for random orientation, where $\langle P_2(\cos\theta_\mu)\rangle$ and $\langle P_2(\cos\theta_c)\rangle$ are both zero, $\langle\cos^2\theta_c\rangle$ is 1/3; whereas, for perfect uniaxial orientation $\langle P_2(\cos\theta_\mu)\rangle$, $\langle P_2(\cos\theta_c)\rangle$ and $\langle\cos^2\theta_c\rangle$ all equal unity.

7.2.3 Applications

Orientation measurement experiments may be made on pre-stretched samples or series of samples, i.e. in a static mode, or they may be undertaken in a dynamic sense, in which stretching and infrared measurements are made essentially simultaneously, see also section 12.

7.2.3.1 Static Measurements of Molecular Orientation One of the most extensively studied polymers has been the commercially important PET[65,66,70,73,76,77,79–81,84–90] In PET, as the polymer chains are extended then the glycol unit can undergo a conformational change from the gauche to the more extended trans form. Specific $\langle \cos^2 x_i X_j \rangle$ values may be interpreted to describe preferential orientation of the aromatic rings into the sample plane, or preferential orientation of the chain axis with respect to the sample axes. Figure 10 shows some of the key bands (see Table 1) used in studies of molecular orientation in PET.

Figure 10 Polarized infrared absorbance spectra recorded from a uniaxially drawn PET. Upper spectrum, electric vector aligned perpendicular to film draw direction; lower spectrum, electric vector aligned parallel to film draw direction. The spectra have been offset for clarity.

1894	σ	C
1368	π	A
1352	π	A
~1305	π	A
1078	σ	A

Since in PET extended trans sequences of chains may crystallize, for measures of molecular orientation it is important to decouple the effects on the infrared spectrum of orientation from those of crystallization. If different conformers may be associated with different phases, then the orientation of individual phases can be measured. For example, in a study of orientation development in low density poly(ethylene) (LDPE) blown films crystalline order has been associated with bands at 1050 cm^{-1} and 1175 cm^{-1};[91] the modes giving rise to these bands have transition moments along the chain axis. For studies on thicker samples, such as sheet and tube walls, then other weak bands have been used to determine orientation levels for both amorphous and crystalline phases,[73,92–94] see Table 2. Many studies of both uniaxial and biaxial molecular orientation have been undertaken on a diverse range of polymers, polymer systems and rubbers. Some additional references are given in Table 3.

7.2.3.2 Dynamic (Rheo-optical) Measurements Rheo-optics is a term used to define a combined mechanical test with an optical measurement.[111,112] Simultaneous stress–strain and infrared data are recorded during polymer elongation in rheo-optical FTIR experiments. The sample, usually in film form, is clenched between the jaws of a tensile stretcher device mounted in a temperature controlled accessory sited into the sample compartment of an FTIR spectrometer. Sequential FTIR spectra are then recorded coincident with stress–strain data as a function of strain (and/or time). Interferograms over short time intervals are acquired with radiation polarized alternately parallel and perpendicular to the elongation direction. Deformation during elongation and subsequent relaxation under constant strain processes may both be monitored, as may structural changes during loading–unloading cycles.[9] Some references to rheo-optical FTIR studies are given in Table 3.

7.3 End Groups, Branching

End group balance or type and short side-chain branches are important characteristics of a polymer. They can

have a major influence on polymer morphology and properties, affecting stability, processability and application. Their detection, identification and quantification may sometimes be simply accomplished by infrared spectroscopy. (Long chain branching cannot usually be appropriately studied by infrared spectroscopy.) If not readily discernible or measurable, the contrast of bands characteristic of end groups may need to be enhanced. This may be achieved in a number of ways. A common approach is the use of difference spectroscopy, in which the spectrum of a higher molecular weight polymer is spectrally subtracted from that of a lower molecular weight polymer, or two polymers of similar molecular weight but with different end group types. Other approaches may invoke derivatization or, particularly for hydrogenated end groups, the use of isotope exchange. Two classic examples of end group measurements by infrared spectroscopy are the determination of the methyl group concentration in poly(ethylenes) and the carboxyl and hydroxyl end group concentrations in PET.

LDPE and high density poly(ethylene) (HDPE) may be distinguished readily in their infrared spectra by the intensity of the 1378 cm^{-1} absorption band, which is attributable to the methyl symmetric bending mode, $\delta_{sym}(C-CH_3)$. In HDPEs the methyl groups are present essentially as end groups.[120,121] They are therefore characterized by relatively low concentrations of methyl groups, typically <10 methyl groups per 1000 C atoms; whereas in LDPEs, which contain a much higher concentration of side-chains, the methyl group concentration may typically lie between 20 and 30 per 1000 C atoms. Figure 11 illustrates this typical distinguishing feature between an HDPE and an LDPE. The traditional way of determining the intensity of this band has been by spectral subtraction (difference spectroscopy), in which the overlapping absorption bands at lower wavenumbers due to methylene group wagging modes, $\gamma_w(CH_2)$, are minimized, using a polymethylene or HDPE of very low methyl content for the compensation.[120,121] Further differentiation between the infrared spectra of HDPE and LDPE may often be confirmed in the pattern of bands between 1000 and 850 cm^{-1}, which are the out-of-plane deformation modes of the hydrogen atoms associated with the olefinic unsaturated groups at the chain end or in the polymer chain. Their relative intensities vary with the mode of manufacture and catalyst system used. In many LDPEs the absorption band at 888 cm^{-1} due to vinylidene (pendant methylene) groups is the more intense. This is in contrast to many HDPE spectra, in which the most prominent band is the 910 cm^{-1}, which arises from the terminal vinyl group, $-CH=CH_2$, which has a weaker partner at 990 cm^{-1}. The other key band in this region is that due to the chain unsaturation group $-CH=CH-$ which occurs at 965 cm^{-1}. These simplistic comparisons between LDPE and HDPE become much less straightforward when the infrared spectra of linear low density poly(ethylenes) (LLDPEs) are considered. In LLDPEs short-chain branches are introduced into the polymer chain by copolymerizing ethylene with low levels of an α-olefine, such as propene, butene, hexene, octene or 4-methyl pentene-1. The position, half-width and absorption coefficient of the methyl symmetrical deformation band near 1378 cm^{-1} is dependent on the

branch type.[122,123] The position of the methyl rocking band that occurs in the region 880–940 cm^{-1} is also characteristic of the type of branch. However, these bands are overlapped by those of the out-of-plane deformation modes of the hydrogen atoms of the olefinic unsaturated groups. Their position may be ascertained through following careful and safe bromination, which saturates the double bonds.[122–124]

Specific end-capping of a polymer may be the key to imparting thermal stability. Such processes may in some circumstances be monitored by infrared analysis. In nascent copolymers of tetrafluoroethylene/hexafluoropropylene (TFE/HFP) unstable end groups may be identified and their concentrations quantified through their infrared absorption bands.[125–127] Monomeric and dimeric $-CO_2H$ groups, which give rise to absorption bands at 5.52 μm and 5.64 μm (1812 $cm^{-1}$and 1773 cm^{-1}), respectively, may be decarboxylated by appropriate treatment to the more stable $-CF_2H$ end, which absorbs near 3.32 μm (3012 cm^{-1}). Vinyl ends ($-CF{=}CF_2$), absorbing in the infrared at 5.57 μm (1795 cm^{-1}), are also a potential cause of thermal instability in these copolymers. These may be oxidized during processing to $-COF$ ends, which are characterized by an absorption band at 5.31 μm (1883 cm^{-1}).

The sensitivity of infrared spectroscopy to $-OH$ vibrations makes it particularly well suited to monitoring or determining these types of end groups. A well established quality assurance method is that of measuring the end group balance in PET, which may be synthesized commercially by a polycondensation between ethylene glycol and terephthalic acid. The resulting hydroxyl and carboxyl end groups may be determined from measurements of the (sample thickness) normalized absorption intensities at 3542 cm^{-1} and 3256 cm^{-1}, respectively.[128–130] These may be correlated against absolute determinations from NMR and chemical titration methods, respectively. Their absorption maxima may also be highlighted by deuterium exchange, see Figure 12. Similarly, infrared methods have been developed for determining the hydroxyl and carboxyl end group concentration and therefore the number-average molecular weight in poly(butylene terephthalate) (PBT),[131] and poly(ethylene naphthalene-2,6-dicarboxylate) (PEN).[132]

7.4 Hydrogen Bonding

The properties of many polymers and copolymers depend on their physical network. Since infrared spectroscopy is an excellent tool for observing hydrogen bonding and studying its temperature dependence behavior, many detailed studies have been undertaken on polymer and rubber systems. In particular, several studies have focused on self-association mechanisms in polyamide,[133–137]

Figure 12 End groups in PET. (a) Overlaid spectra of dried PET film before and after deuteration. (b) Difference spectra between the films before and after deuteration highlighting postions of hydroxyl and carboxyl end groups.

PU[138–143] and polyurea[144,145] systems, many of which have included related work on model compounds. Also, study of inter-association bonding processes between two different polymers has been the subject of considerable investigation, with particular reference to polymer–polymer mixing and miscibility. Coleman et al.[146] provide a comprehensive monograph on the latter. Blend miscibility studies are discussed in more detail in the next section.

Temperature dependence studies of the νNH region of polyamides,[133–137] coupled with restricted curve-fitting procedures,[136,137] have led to the overlapped band envelope observed in this region being assigned as being composed of contributions from two species. These were a ''free'' N–H and hydrogen-bonded N–H stretching modes at room temperature, occurring at ca. 3445 cm^{-1} and ca. 3300 cm^{-1}, respectively. Systematic changes were observed for these bands with increasing temperature, with a shift to higher wavenumber noted for the hydrogen-bonded band. For the Amide I region (νC=O), three bands were discerned at room temperature. These are, a band ascribed to ''free'', non-hydrogen-bonded, carbonyls and a band from disordered hydrogen-bonded carbonyl groups; and for semi-crystalline nylons, an additional band arising from ordered hydrogen-bonded carbonyl groups, showing an observable sensitivity of the Amide I band to conformation. Again, systematic temperature dependent intensity changes and wavenumber shifts were observed for these bands. The spectra shown in Figure 13 illustrate the data recorded from such an experimental study. Similar approaches have led to the assignments of the various bands contributing to the νN–H and νC=O band profiles observed with PUs[138–143] and polyureas.[144,145]

7.5 Blend, Miscibility Studies

Enhancing product ranges through polymer and/or rubber blending has a long commercial history. Blend properties are strongly dependent on the state of mixing. If the polymers are not miscible, which implies that they do not interact at a molecular level to form a compatible mixture, then they will likely phase separate and exhibit poor mechanical performance.[1] Infrared spectroscopy is a prime tool for detecting and probing the interactions and structure of polymer and rubber blends, and FTIR studies are reported extensively in the literature. The reader is recommended to the books by Garton[5] and Coleman et al.,[146] and the study by Coleman & Painter[147] for detailed discussions.

The infrared spectrum of a blend of two incompatible homopolymers will be equivalent essentially to the summation in appropriate proportion of the individual infrared spectra of the two components. Specific intermolecular interactions, such as hydrogen-bonding or polar coupling, may be detected through band position shifts and intensity modifications. The most widely reported are those associated with the perturbation of a carbonyl stretching vibration of one polymer by hydrogen-bonding with the other polymer, which leads to a reduction in the wavenumber position of this absorption band in the infrared spectrum of the blend, see example in Figure 14.

Infrared temperature dependent experimental observations have been made on several blend systems over a range of compositions and associated homopolymers designed to aid elucidating inter-polymer associations from self-association absorption contributions. The experimental data have been analysed with data manipulation procedures such as curve fitting. From such investigations, the fractions of hydrogen-bonded groups have been estimated and thence, for some, equilibrium constants of association have been calculated. These data have then been used to map phase diagrams and predict miscibility windows for polymer blends.[148–154]

The data processing techniques of factor analysis, difference spectroscopy and least-squares curve fitting have been applied to the infrared spectra recorded from cast films of a series of PVdF and poly(vinyl acetate) (PVA) blends.[155] Factor analysis from temperature experiments was used to establish compatibility or incompatibility. An ''interaction spectrum'' was then derived through a least-squares difference spectroscopy procedure, by subtracting the contributions to the infrared spectrum of the pure homopolymers. The percentage contribution of the ''interaction spectrum'' appropriate to each blend composition was determined by a least-squares analysis and followed throughout heat treatment ageing processes.

Figure 14 Infrared absorbance spectra at room temperature recorded in the carbonyl stretching region from films of pure EVA copolymer (33 wt% VA vinyl acetate) and blends containing 80, 60, 40 and 20 wt% PDMVPh, poly(2,6-dimethyl-4-vinyl phenol) and PDIPVPh, poly(2,6-diisopropyl-4-vinyl phenol). The lower wavenumber band is a consequence of hydrogen bonding between the blended materials. (Reprinted from G.J. Pehlert, X. Yang, P.C. Painter, M.M. Coleman, 'Self-association Versus Interassociation in Hydrogen Bonded Polymer Blends: 2. Comparison of Theoretical and Experimental Miscibility Windows for Poly(2,6-dialkyl-4-vinyl phenol) Blends', *Polymer*, **37**, 4763–4771 © (1996), with permission from Elsevier Science.)

The strong modulus in the rubbery zone of heat processed acrylamide (AA)-grafted silicone and maleic anhydride modified ethylene–propylene–diene monomer (EPDM) blends has been attributed to chemical interactions from observations made from the νC=O region of their infrared spectra.[156] In a study in which differential scanning calorimetry (DSC) and temperature dependent FTIR were combined to investigate blends of polyisoprene with poly(*cis*-butadiene-co-1,2-vinyl-butadiene), FTIR experimental data were used to detect microstructures that relate to transition temperatures of sequences in the polymers, and postulate that polyisoprene segmental movement onset occurs before that of segments associated with the other polymer, accounting for the broadened DSC observed transitions for the miscible blends.[157]

7.6 Copolymer Composition

Copolymers may be thought of as polymers with chain structures in which chemically different monomer units are linked in different concentrations in a "non-uniform" manner;[12] to a large extent this "non-uniformity" will likely have been designed to produce products with differing chemical or physical properties. An example, that of propylene/ethylene copolymers, has already been outlined in the introduction to section 7. Determining quantitatively copolymer component concentrations by infrared spectroscopic methods is a major analytical application area. Routine, cost-effective methods are widely developed and used for product composition quality assurance within industry. At the simplest level, it involves recording the infrared spectra in an identical manner from a series of copolymers of differing but known compositions, which cover the specification range of interest. From these, it may be possible to assign uniquely non-overlapped absorption bands to a particular copolymer component. The normalized absorption intensity of such a band arising normally from the presence of the lower concentration component is then correlated with comonomer composition. If the method is to be used over a wide concentration range and/or for copolymers prepared possibly by different synthetic routes, then it will be particularly important to ascertain whether the absorption bands are position and shape sensitive to co-monomer sequencing and sequence lengths.[1] For precise, robust procedures, particular care will also have to be exercised in the choice and specification of the method of sample preparation and presentation. These must be reproducible, in order to minimize any band intensity variations that may occur

with changes in copolymer morphology or conformation, or that may be directly related to optical artifacts associated with the sampling technique. Many reliable, simple to operate, multicomponent analyses involving overlapping infrared absorption bands have now been developed and implemented through the use of multivariate regression procedures, such as PLS analysis. While these analyses may be more complex, similar criteria still apply, in that due consideration must still be given to effects associated with sequencing, crystallinity, and sampling.

Approaches to compositional analyses of copolymers for quality assurance will depend on many factors, including specimen presentation method and spectral complexity, but particularly concentration range and precision requirement. For example, in a standard method by the American Society for Testing and Materials (ASTM)[158] copolymerized ethyl acrylate content in the range 1–25 wt% present in ethylene–ethyl acrylate copolymers is calculated from a determination of the absorbance at 11.6 μm (862 cm^{-1}) per mm of film thickness for films of thickness between 0.18 and 0.5 mm; whereas in another published method[159] a ratio of absorbance integrals of the ν–C=O first overtone band at 3450 cm^{-1} to that of 2750–2450 cm^{-1} (CH) were determined over an extended range from films of similar optical path length. Both methods report high precision, e.g. ±3 mol%.[159] Four ASTM standard methods have been described as being required to deal with commercial ethylene–propylene copolymers and ethylene–propylene–diene terpolymers in the range 35–85 mass % ethylene.[160] For an ethylene–propylene–diene terpolymer system containing diene in the range 0.1–10 wt%, diene compositions were determined from normalized second-derivative spectra.[161] Many, simple to implement fit-for-purpose

Figure 15 Infrared analysis of TFE/HFP (hexafluoropropylene) copolymers. copolymer compositional methods have been described by Haslam et al.[2] and Zichy.[162]

Figure 15 shows a band ratio DRIFT method evaluated for dealing directly with TFE/HFP copolymer powders.[27,163] It was developed from the more routine transmission approach, which made the measurements on coalesced disks, see section 3.1.3. Figures 16–18 outline some simple examples of quantitative procedures that have been developed for copolymer composition. Figure 16 illustrates a transmission procedure for determining from cast films the composition of copolymers of aryl–ether–sulphone and aryl–ether–ether–sulphone.[164,165] In Figure 17 an example is shown of a compositional measurement made on a compression-molded EVA copolymer film.[166] A number of potential simple quantitative PA-FTIR methods for rubber compositions have been reported.[167] Figure 18 shows some ethylene oxide/propylene oxide (EO/PO) copolymer spectra recorded on a ZnSe internal reflection element, which were the subject of a successful PLS treatment.[165] Infrared absorbance measurements of bands characteristic of unsaturated species have been used to study the degree of hydrogenation in nitrile-butadiene rubbers[168,169] and composition of butyl and halo-butyl rubbers.[170] In each the primary method used was NMR.

Many additive concentrations and filler levels may be determined in polymer and rubber formulations by similar analytical procedures to that used for copolymer composition.

Figure 16 Infrared absorbance spectra recorded from solution (1,1,2,2-tetrachloroethane) cast thin films onto KBr polished plates of a poly(aryl-ether-sulphone) (PES), bottom trace, and two aryl-ether-sulphone/aryl-ether-ether-sulphone copolymers, middle and upper traces. Copolymer compostion may be determined from a measurement of the absorbance ratio, 1190 cm^{-1}/1010 cm^{-1}.

7.7 Polymerization and Cure Studies

Infrared spectroscopy is a valuable tool for studying and monitoring polymerization processes and cure mechanisms. In some cases, time-dependent or temperature-dependent kinetic profiles may be derived by simply using a dispersive or filter spectrometer set to monitor continuously at a characteristic fixed wavenumber the absorption intensity of a functional group, which is either associated with a particular monomer starting material or attributable separately to a product. However, it is now more usual to use a rapid scan FTIR system to record sequential time-lapse spectra, from which measurements may be determined of functional group concentrations at predefined time intervals.

Although prior to ca. 1990 there were frequent reports of the use of infrared spectroscopy for monitoring bulk polymerization processes, these presented considerable

Figure 17 FTIR absorbance spectra recorded from compression molded films (ca. 100 μm thickness) of two EVA copolymers containing 7.7 wt.% and 28.6 wt.% VA units. Potential bands for compositional determinations are the VA absorptions near 3460 cm^{-1} or near 610 cm^{-1}.

Figure 18 Overlaid FTIR/ATR absorbance spectra, each in duplicate, recorded from two different EO/PO copolymers, containing ca. 72 wt.% and 84 wt.% EO. (Reproduced from J.M. Chalmers, N.J. Everall, 'FTIR, FT-Raman and Chemometrics: Applications to the Analysis and Characterisation of Polymers', *Trends in Analytical Chemistry*, **15**, 18–25 © (1996), with permission from Elsevier Science.)

practical difficulties. Not least of these was that one had to try to mimic conventional laboratory or production synthesis conditions while undertaking the polymerization and spectroscopic measurements in temperature and pressure controlled narrow path length transmission or internal reflection liquid cells. Many of these problems were overcome with the introduction of immersion probes for use in the mid-infrared region. These probes, based on the internal reflectance principle, can be coupled to FTIR spectrometers through transmitting conduit (hollow metallic light guides). They may be used for the real-time analysis of liquid or melt, either batch or continuous, reactions, and adapted for use with both laboratory-scale or plant vessels.[171] Figure 19(a) and (b) show schematics of a probe sensing head construction and an experimental laboratory scale arrangement.[171]

By contrast, many thermal cure mechanisms may be investigated readily by transmission or internal reflection infrared measurements from thin films cast from resin solutions. Thermoset resins based on cure of

Figure 19 (*Continued*)

epoxy resin formulations are a very important class of materials industrially, particularly as matrices in advanced materials such as fiber-reinforced composites. Their properties depend on the degree of cure and structure of the epoxy matrix, both of which may be investigated beneficially by infrared spectroscopy.[172,173] Homopolymerization and cross-linking reactions may be observed through decrease of the absorption intensity of bands associated with the glycidyl group, most commonly that near 910 cm^{-1} attributed to the epoxy ring,[174–176] although the position of this characteristic vibration of the oxirane ring varies with ring substitution. Additionally, many other changes of absorption intensities of characteristic functional group bands, such as those of hydroxyl, amine, ether, anhydride and ester may be readily observed and related to the mechanisms of cure and cross-linking imparted by the resin formulation components.[177,178]

Polyimides are another important class of high-temperature resistant polymers. As with epoxy systems, because of their functionality infrared spectroscopic analysis can provide considerable insight into polyimide formation and cure. Reaction mechanisms of an aromatic dianhydride or multi-basic aromatic acid (e.g. pyromellitic acid) with an aromatic diamine to form the polyamic acid may be characterized readily. Cyclization to imide formation during thermal curing of this prepolymer and subsequent cross-linking may also be observed; increasing ring closure to imide is readily seen by increasing intensity of its $\nu_{sym}C{=}O$ band near 1780 cm^{-1},[179–182] see Figure 20.

PUs are formed essentially from the reaction of di- (or poly-) isocyanates with polyhydric alcohols, or, in the case of polyester or polyether urethanes, with polymers having terminal alcoholic groups. Their commercial range extends from simple linear aliphatic elastomers, through two-component cross-linkable aromatic–aliphatic coating formulations, to complex resins involving many ingredients designed when mixed to produce foams with different cellular structures and physical properties. Infrared has been used extensively to both analyse the molecular structure of PUs and probe the

Figure 20 Infrared absorbance spectra of a spin-coated thin film onto a NaCl disk of a polyimide (pyromellitic dianhydride + 4.4′diamino diphenyl ether) at three stages of cure. (Reproduced from Snyder[179]. (Permission applied for).)

chemical reaction rates and morphology associated with cross-linking and foaming processes. Residual isocyanate may be determined quantitatively from a measure of the band intensity of the N=C=O stretching band at 2270 cm^{-1}.[183] In addition to this absorbance, infrared analyses usually focus on three other spectral regions: the νN−H region between 3500 and 3200 cm^{-1}, the Amide I (or carbonyl) region between 1800 and 1600 cm^{-1}, and the Amide II region below 1600 cm^{-1}.[140,184,185] These regions, while very informative, may not be straightforward to evaluate.[140,185] They often consist of many overlapping bands, since, for example, the reaction processes and products of a water-blown foam may include species such as urethanes, ureas, amides, allophanates, biurets, carbodiimides and isocyanurates, which associate eventually to form a polymeric network with a multiphase molecular morphology.[184] Similar complexities also apply for urea-based resins with formaldehyde, for which similar infrared analysis considerations can aid elucidation of structure and cure mechanism.[186]

Special cells that incorporate multiple IRS crystals have been used to monitor the chemical species changes that occur during PU foaming in order to help understand foam behavior.[187,188] Time correlations of isocyanate conversion and evolution of urethane, urea and hydrogen-bonded species were developed from infrared absorbance measurements.[187] Experimental measurements have also been made in which the sensor is a declad portion of a mid-IR transmitting fiber-optic. This is coated or surrounded by resin and thermoset cure monitored. The unclad portion of the fiber provides for evanescent wave (internal reflection) spectroscopy.[189–192] A variety of fiber materials have been used, and several resin, composite and prepreg cure systems sensed in situ. These include both polyimide/graphite and epoxy/graphite systems[191,192] and epoxy adhesives and a urethane resin.[192] A similar approach was utilized to provide for measuring in situ, in-mold kinetics in reaction injection molding (RIM) processes.[193]

Another key area for infrared analysis of cure chemistry is that of measuring the degree of cure and studying cure behaviour of UV curable resins. Real-time (dispersive IR, set at a fixed wavenumber)[194–197] or quasi-continuous (FTIR)[198–200] in situ radiation cure monitoring has been reported for many acrylate based resin formulations, in which both the unreacted monomer and/or residual photoinitiator levels may be determined. Degree of cure and conversion profiles may be assessed by the decrease in intensity of absorption bands of the acrylic monomer vinyl group, notably the νC=C near 1640 cm^{-1} and the C−H deformation mode near 810 cm^{-1}. Transmission,[198] internal reflection[199] and reflection–absorption (transflectance)[200] approaches have been reported, in which the UV cure was carried out in situ in the spectrometer sample compartment. The time-slice resolution of FTIR observations was of the order of 0.5 s.

7.8 Degradation and Oxidation

The sensitivity of mid-infrared spectroscopy to oxygenated functional groups makes it a particularly useful technique for monitoring the molecular species formed or undergoing change in polymers as a consequence of thermal, thermal-oxidative, photo, photo-oxidative and radiation induced damage or modification, whether they be surface or bulk effects.[201] Particularly rewarding has been the study of the degradation processes of aliphatic hydrocarbon polymers, especially polyethylene. For polyethylene, hydroperoxide formation, a primary step (induction period) in the autocatalytic process of polyolefine oxidation, may be observed as an absorption feature at 3555 cm^{-1}, prior to the generation of a variety of carbonyl and hydroxyl species.[202–205] These have absorption band envelopes in the 1750–1690 cm^{-1} (νC=O) and 3600–2800 cm^{-1} (ν−OH) regions respectively. Accompanying these oxidative pathways are changes in the relative intensities of absorption bands associated with unsaturation groups, most notably absorption bands that occur between 1000 and 880 cm^{-1}. Thermal oxidation leads primarily to a reduction of the band characteristic of vinylidene unsaturation (>C=CH_2) at 888 cm^{-1}. Photo-oxidation is characterized by an increase in vinyl end groups (−CH=CH_2), which is associated with a pair of bands at ca. 990 and 910 cm^{-1}, the latter being about

three times the intensity of the former. Absorbance subtraction has been employed to highlight subtle differences in degradation behavior for polyethylene when γ-irradiated in oxygen and nitrogen atmospheres.[206] Quantitative estimation of the absorbance species summing to the ν−C=O band envelope in oxidatively degraded polyethylene has been based on a band deconvolution procedure.[207] Further confirmation of some of the species formed or elucidation of certain of the mechanisms of degradation may be achieved through derivatization or treatment with particular reagents. For example, acid carbonyls in oxidized polyethylene may be converted to carboxylate salts by alkali treatment, with a consequent shift of the saturated carboxylic acid peak at ca. 1710 cm^{-1} to a peak characteristic of a $-C(=O)O^-$ at ca. 1610 cm^{-1}, while SO_2 treatment has shown that hydroperoxidation probably takes place in the chain in the α-position to a pendant methylene (vinylidene) group.[204] Ammonia, SF_4 and NO were all used to derivatize thermo-oxidatively-degraded heterophasic ethylene–propylene copolymers to facilitate understanding of the degradation pathways,[208] and NH_3, SF_4 and NaCl chemical treatments were all used to aid analysis of structure modifications introduced during photo-oxidation of anhydride-cured epoxy resins.[209]

An FTIR analysis, including the use of FTIR-microscopy, of photo-oxidized films of polybutadienes with differing relative concentrations of stereoisomers suggested that stereospecificity per se had little effect on the kinetics of photo-ageing. Irradiation of the film sets up extensively oxidized, cross-linked surface layers, which prevent further ingress (diffusion) of oxygen, and the core of the films remain largely unmodified.[210] However, all these films had high concentrations (>55%) of 1,4-double bonds. In contrast, for a 1,2-polybutadiene (84% 1,2-) no photo-passivation occurred and a much lower rate of photo-oxidation was observed, accounting for its photo-degradability.[211] These examinations involved monitoring and profiling by infrared spectroscopy absorption bands due to carbonyl, hydroxyl and unsaturated groups. In another study of thermo-oxidative degradation, FTIR/ATR was employed to examine thick-walled cylinders of vulcanized natural rubber materials.[212] Again, the observed ageing processes were dominated by the formation of an adventitious oxidized layer, which having low permeability to oxygen protected the interior material. Derivatization was used to aid an investigation of the γ-irradiated initiated oxidation of a random acrylonitrile–butadiene copolymer rubber.[213] SF_4 converted all carboxylic acids to acid fluorides, resulting in a νC=O band shift from ca. 1740 cm^{-1} to 1841 cm^{-1}; NO converted −COH groups to nitrites, while hydroperoxide groups were converted to nitrates, with corresponding changes observed in the infrared absorption features.

In an FTIR investigation into the influence of the radiation dose and the hydrolysis conditions on the chemical structure of PTFE, transmission, diffuse reflectance and photoacoustic sampling were used.[214] The authors concluded that changes observed in the relative intensities of bands between the transmission (bulk phase) and those of the more near-surface sensitive techniques demonstrated that hydrolysis of the −COF groups to −COOH is preferred in the near-surface regions of the irradiated PTFE particles. The former groups were observed at 1884 cm^{-1}, the latter at 1776 cm^{-1} (associated dimer) and 1792 cm^{-1} (H-bonded to water).

The *in vacuo* thermal degradation up to 500 °C behaviours have been compared for a PVA, a poly(methacrylic acid) (PMAA), and a vinyl acetate/methacrylic acid (VA/MAA) copolymer having 65% alternating units.[215] Films of the sample ca. 50 μm thickness were cast onto reflecting stainless steel plates, and their spectra measured by reflection–absorption (transflectance). For PVA, changes in the infrared spectrum beginning at 160 °C may be associated with the formation of −C=C− (3020 and 1657 cm^{-1}) as acetic acid is eliminated. With increasing temperature polyenes are formed, then cross-linking and aromaticization occurs (bands observed at 3020, 1600, 1560, 1520, 1450, 760 and 700 cm^{-1}), with the ester (1740 cm^{-1}) being converted to a ketone (1706 cm^{-1}) above 440 °C. For PMAA, programmed heating leads to formation of anhydride peaks in the infrared spectrum at ca. 1804 and 1765 cm^{-1}. Continued heating leads eventually at 440 °C to a condensed ring aromatic char. For the VA/MAA copolymer, anhydride rings begin to form at 200 °C and then decompose as for PMAA. At 280 °C, lactone formation (1775 and 1203 cm^{-1}) between adjoining VA and methacrylic acid (MAA) units is observed. These have decomposed by 480 °C when the material is again essentially a highly substituted aromatic ring char.

Sequential changes observed in an FTIR thermal oxidative degradation study of nylon at 200 °C showed similar changes for both nylon 6 and nylon 6,6, with a decrease in intensity of every peak related to the amide groups and production of new carbonyl groups.[216] In a photo-oxidative study of these nylons similar spectral changes were observed, suggesting similar degradation mechanisms.[217] Difference spectroscopy was used in both studies, with infrared spectroscopy being used also to identify the gases evolved from the photo-initiated degradations. Comparative infrared studies on thin films of the thermal degradation under reduced pressure of polyacrylonitrile (PACN) and acrylonitrile copolymers with VA, MAA and AA made apparent that the rate of degradation is dependent upon the specific type of comonomer introduced into the acrylonitrile polymer chain.[218] The species monitored was the production

Figure 21 MIR spectra recorded from the surfaces of an artificially UV aged (120 h) PET film. (a) Spectrum of the film surface facing away from the UV source. (b) Spectrum of a surface before exposure to the UV radiation. (c) Spectrum of the film surface facing the UV source. Two KRS5 MIR prisms were used: a 45° angle of incidence set-up to enhance the intensity in the high wavenumber region, and a 60° angle of incidence prism for the region 2000–400 cm^{-1}.

of the cyclized pyridone structure, characterized by the appearance and growth of a doublet at 1610/1580 cm^{-1}, and loss of ν–C≡N at 2240 cm^{-1}. The rate of degradation increased as PACN < ACN/VA < ACN/AA ≈ ACN/MMA. Degradation process mechanisms were elucidated for each copolymer from further infrared studies: ACN/MAA,[219] ACN/VAc[220] and ACN/AA.[221]

The photoproducts of polystyrene irradiated by both short (253.7 nm) and long wavelength (≥300 nm) in atmospheric oxygen have been identified by infrared spectroscopy[222] and profiled through the photoxidized films by infrared microspectroscopy.[223] The products were characterized by a combination of approaches that included difference spectroscopy, derivatization with SF_4 and NH_3, solvent extraction with methanol, thermolysis and photolysis, coupled with model compound studies. Although the products formed at the two irradiation treatments were the same, their relative concentrations were different.[222] A wide range of –OOH, –OH and –C=O containing photoproducts were reported as being identified, both evolved as molecular compounds or as features of the degraded polymer chain. For photo- and

thermo-initiated oxidation of high-impact polystyrene, changes occurring in the FTIR spectra suggested that the first step in the degradation process involved preferential oxidation of the polybutadiene segments that had been grafted onto the polystyrene units.[224]

For surface layer specific products, providing the sample retains a reasonably smooth texture, internal reflectance spectroscopy may be used to highlight surface degradation chemical products.[20] An example is shown in Figure 21. For sealant or protective polymer coatings on metal substrates, reflection–absorption[225] or photoacoustic[226,227] methods may be used conveniently to observe degradation process and accelerated weathering induced infrared spectral changes. Analysis by diffuse reflectance can facilitate certain degradation studies of a polymer–carbon or polymer–glass composite.[228]

8 CHROMATOGRAPHY AND FOURIER TRANSFORM INFRARED

The combination of separation techniques such as liquid chromatography (LC)[229–232] or gel permeation chromatography (GPC) and size (sometimes termed steric) exclusion chromatography (SEC)[232–236] with FTIR analysis has particular value to investigations associated with determining the formulation or compositional heterogeneity of plastic and rubber materials.[229–236]

Organic additives, along with low molecular weight polymer, may be separated from the bulk material by solvent extraction. This extract may then be separated into its components according to their polarity by LC or fractionated according to hydrodynamic volume in solution by GPC. A polymer, a polymer blend or a copolymer composition distribution may be investigated by using SEC/GPC, in which the order of elution is a function of molecular mass. Coupling of these selective techniques with a molecular spectroscopy specificity technique such as infrared spectroscopy can enhance significantly the characterization of a polymer sample, although, because of the infrared absorption intensity of solvent bands, by far the commonest qualitative procedure in each case involves examining the separated fractions after the solvent has been eliminated, rather than in situ in a flow-through cell arrangement. Also, studies are usually limited to separations that do not require the addition of non-volatile buffers, since most of those used are also strongly infrared absorbing.

Various solvent elimination–analyte deposition systems have been developed. The coupling requires that the material presented for IR analysis is deposited onto an appropriate substrate, in a suitable continuous form, in a controlled, synchronized manner, and that it is free from solvent and has not been degraded. Both temperature-controlled spray-jet nozzles and ultrasonic nebulizers have been used as deposition tips. Their effluents are directed to either a linearly translating or rotating, transmission or transflectance support, on which the solute is deposited ideally as a localized, continuous track or series of well-defined spots, with the eluent solvent volatilizing rapidly during the deposition process. The deposited solute is then characterized using either an infrared beam-condensing optics module or under an FTIR-microscope. For transmission measurements, a ZnSe window has been commonly employed as the substrate; while a transflectance system has been commercialized, in which the sample disk is a 2 mm thick Ge disk, which has an aluminium reflective coating on its reverse side.[233,235,236] A schematic of this is shown in Figure 22. Software algorithms, such as the Gram–Schmidt reconstruction, may be used to generate time-based representations of integrated absorption intensities (amount of sample deposited). These will resemble the chromatogram outputs from detectors such as differential-refractive index or UV, but with different relative intensities of the peaks within the profile. Similarly, functional-group profiles as functions of time may be generated. Figure 23 illustrates the types of complementary information that may be recovered from a combined chromatography with infrared spectroscopy analysis of plastics and rubbers. In SEC/FTIR, a drawback is that quantitation at the molecular weight extremes is likely to be very imprecise and problematical, since deposition can change from a thin, continuous film to discontinuous polymer droplets.[235]

In addition to the LC/FTIR characterization of additives,[229–232] the potential has been demonstrated of capillary SFC-FTIR[237] for identifying similarly the components of additive packages, to similar levels of ca. 100 ng. With SFC-FTIR, the volatility of supercritical CO_2 makes solvent elimination simple; deposited fractions may be examined in transmission with an FTIR-microscope system. Diffuse reflectance procedures from material transferred from thin-layer chromatography (TLC) separated fractions may also be employed to fingerprint the solvent extracted components of additive formulations from polymer samples,[238] to levels of 20 μg or less. On-line thermal desorption in series gas chromatography (GC)/FTIR and GC/MS (mass spectrography) has been used to identify building blocks (depolymerization products, residual monomer) in plastic optical fibers.[239]

9 PYROLYSIS AND INFRARED

Implying the chemical structure of a polymer or rubber through depolymerization or decomposition by

examining the infrared spectra of its volatilization or pyrolysis products is a well-established method. Under controlled conditions, for example, a polyester urethane will cleave to yield the diamine, diol and diacid.[9] While pyrolysate spectra have not always been reproducible, and in many instances their spectra are not explicit enough for unambiguous material identification, these methods have particular value towards identifying intractable, heavily inorganically filled, or cross-linked polymers and rubbers.[2,12] Two approaches are essentially employed.

Figure 23 SEC/FTIR. (a) 3D display of absorbance infrared spectra recorded from components separated by SEC of a commercial adhesive. (b) The material that eluted at 8.4 min was identified from its infrared spectrum as a styrene/isoprene block copolymer. This figure also compares an IR chromatogram reconstructed from total absorbance values with that integrated over only the 1600 cm^{-1} band. (c) Similar data for the peak eluting at 17.9 min, characterized as essentially an aliphatic ester. (Figures reproduced from Willis et al.[236] by kind permission of Gordon and Breach Publishers, Lausanne, Switzerland, © 1997.)

The first captures the pyrolysate for a condensed phase analysis; the second examines the evolved gases, either directly or following separation in a GC.

Spectra have been offset for clarity and scaled to similar maximum intensity values. (Reproduced from M. Pellow-Jarman, M. Hetem, 'Comparison of the Thermal Degradation Products of Poly(butylene Terephthalate) and Flame Retardant Poly(butylene Terephthalate) Formulations Using a Pyrolysis FTIR Cell', *Polymer Degradation and Stability*, **47**, 413–421, © (1995), with permission from Elsevier Science.)

Several simple experimental set-ups for generating and trapping evolved volatiles and decomposition products have been reported. These have included filament heating at ca. 750 °C in an appropriate tube immersed in an ice bath. Other approaches, with appropriate attention to safe-handling and protection, have been the heating of a small amount of a sample placed at the bottom of either a test-tube[16,240,241] or a glass melting-point tube;[242] the vapors condense at the walls of the cooler ends of these tubes. Pyrolyzed or volatilized, condensed material is then transferred and transmission sampled in an appropriate way such as a KBr disk or as a deposit on a salt window. In the capillary tube method, a high spectral contrast FTIR micro-KBR disk spectrum was reported of the pyrolysate from 100 µg of a black polyester thread.[242] In such experiments, an infrared spectrum recorded from the involatile residues may be useful in producing a spectrum characteristic of any inorganic filler present in the original sample. Fractional distillation has been employed to separate elastomer pyrolysates from organic additives, prior to identifying both the resin and additives by infrared analysis.[243]

Direct-pyrolysis FTIR, in which the pyrolysis probe is positioned inside an appropriate infrared transmission gas cell sited in the sample compartment of an FTIR spectrometer, allows for in situ analysis of the volatiles.[244–246] External shut-off valve ports on the cell allow for purge, atmosphere or sweep gas entry and exit. Both pulse (instantaneous) pyrolysis and time resolved analysis using

programmed heating experiments are possible. Examples of the infrared data generated from a pyrolysis experiment are shown in Figure 24.

Pyrolysers may also be interfaced to a light-pipe for direct evolved gas analysis (EGA) or via a GC column for a GC/FTIR measurement of volatiles.[247,248] For example, the effluent from a thermal decomposition of 1 mg of polymer sample pyrolysed at 700 °C for 10 s in a Curie-point pyrolyser following programmed GC separation may be fed through a FTIR light-pipe system and then onto a GC flame ionization detector (FID), to accomplish in-series combined analyte information.[248] The potential of such a set-up has been illustrated in a comparison of two butadiene–acrylonitrile copolymers of identical acrylonitrile content, one a block copolymer, the other a statistical copolymer.[248] Examination of the FTIR spectral data showed that the two materials were distinguishable, since formation of acrylonitrile dimer was only observed from the block copolymer, whereas higher relative concentrations of mixed dimers and mixed trimers were obtained from the other material, in accord with its more alternating comonomer sequences.

10 EVOLVED GAS ANALYSIS, THERMOGRAVIMETRIC ANALYSIS AND FOURIER TRANSFORM INFRARED

EGA by FTIR is concerned with the real-time identifying and monitoring by infrared spectroscopy of vapors or gases evolved from certain combustion processes. These may, for example, be evolutions from thermal breakdown experiments in controlled environments,[249–251] or, as mentioned in the last section, pyrolysis vapors, or, even fire gases from direct burning of rubbers or plastics.[252,253] In the study by Kallonen[252] the FTIR spectrometer was equipped with a long path gas cell connected to a cone calorimeter. Thermogravimetric analysis (TGA) is a quantitative technique that measures the change of mass of a sample as it is heated. It is commonly used in the polymer industry to determine weight loss profiles against temperature or time of materials, in controlled atmospheres. Gases or vapors evolving from either an EGA or a TGA[254–260] experiment may be passed through a heated flow-through infrared transmission gas cell for characterization. Typically, this cell will be maintained at a temperature between 200 °C and 300 °C, have a length between 6 and 10 mm; it may be multi-passing, and it will be designed to be inert and minimize condensation of materials onto the cell windows. The time-resolved programmed heating experiment described in the direct pyrolysis discussion in the last section could equally be categorized as an EGA measurement. In the development given by McClennen et al.,[258] the

commercial TG apparatus was interfaced to a standard GC/MS/FTIR light-pipe cell system.

An example of the output from a TGA/FTIR analysis is shown in Figure 25.

11 OPTICAL PROPERTIES AND CONSTANTS

Polymers are used extensively in textiles and in applications such as greenhouse and house glazing, thermal screening, horticulture and as coatings to protect reflector surfaces. Some polymers are fabricated as optical components such as lenses and windows for use in the far-infrared region ($300\,cm^{-1}$ to $1\,cm^{-1}$). For these uses it is important to be able to determine the material optical properties (transmittance, reflectance, absorptance) and optical constants (n, absorption index; k, refractive index). Straightforward, practical methods have been derived for determining many of these; others require more specialized instrumental approaches.

The integrated optical properties with respect to thermal radiation have been determined for a variety of minimal-scattering polymer films using conventional transmission and reflection mid-infrared spectroscopy.[261] For measurements on scattering materials an integrating sphere would have been necessary. The radiative properties of natural and synthetic fibers in the near-infrared (0.25–2.5 μm) region[262,263] and PP fibers[263,264] and powders[264] in the mid-infrared have been studied using an integrating sphere. The mid-IR optical constants for films of PET,[265] PACN,[266] polycarbonate,[267,268] polyimide[269] and PVC, polystyrene and poly(methyl methacrylate)[270] have been determined from FTIR experimental reflectance measurements. For determining the far-IR optical constants of polymer samples the technique of dispersive Fourier transform spectrometry can be utilized.[271] In these measurements, the sample is placed in one arm of a two-beam interferometer. Example results have been reported for poly (4-methyl pentene-1), TPX,[272] and a sailcloth material, a woven PET dipped in PU.[273]

Spectroscopic ellipsometry is a well-proven tool for thin and multilayer solid film sample analysis. The optical properties, n and k, as a function of wavenumber may be derived from analysis of the intensity and phase relationship between the s- and p-components of polarized reflected radiation. In FTIR ellipsometry, a sample surface is normally illuminated in a special accessory at an incidence angle of about 70° with radiation polarized at an angle of 45°. The characteristics (geometry) of the elliptically polarized reflected infrared radiation, i.e. the ellipsometric angles Ψ and Δ, can be used to determine the sample dielectric function and film thickness.[22,274,275] Some examples of applications relating to polymers may be found in the studies by Claybourn,[22] Roseler,[274,275] and Vallon & Drevillon.[276]

12 TWO-DIMENSIONAL INFRARED SPECTROSCOPY

Generalized two-dimensional infrared (2D-IR) correlation spectroscopy is a relatively recent, but powerful, method for analyzing time-dependent variations within a set of spectra.[277–279] It is used to effectively highlight the pertinent spectral features associated with fluctuating or transient infrared data. It can provide enhanced spectral resolution, and simplify the interrogation of a complex set of infrared spectra consisting of overlapping peaks, although presently observations are limited in that they may not be interpreted quantitatively.

Dynamic (rheo-optical) 2D-IR spectroscopy using sinusoidal mechanical perturbation has been used to study excitation–relaxation processes in many polymer systems. Examples are given by Marcott et al.,[278] Meier,[279] Steeman et al.[280] and Singhal & Fina.[281,282] In other 2D-IR studies on polymer systems, the perturbations have included the photopolymerization of acrylic and epoxy monomers,[283] in which transient spectra were recorded with a time resolution of 78 ms, and, equal temperature intervals in a thermal 2D FTIR analysis of a PU elastomer.[284]

2D-IR correlation plots are constructed from perturbation-induced time-dependent spectroscopic responses.[277] The perturbation may lead to spectral changes, such as variations in band intensities, shifts in band positions, or changes in band shape. Individual spectral elements may respond differently to the applied perturbation, and their behaviour with respect to each other is highlighted in a 2D-IR correlation map or correlation spectrum. The output from a 2D-IR correlation analysis is commonly presented as a complementary pair of contour plots of 2D spectra constructed from a dynamic spectrum.[277] This dynamic spectrum is usually displayed as a one-dimensional reference spectrum along the two axes of the correlation plot. The dynamic spectrum is typically selected to be the time-averaged, sometimes the static or original, spectrum of the data set. The synchronous 2D correlation spectrum is a representation of infrared signals that are changing in-phase with each other; in the asynchronous plot, independent and uncoordinated fluctuations of the infrared signal are displayed. Simultaneous or coincident spectral changes measured at ν_1 and ν_2 are located in the synchronous 2D correlation spectrum on the diagonal, as autopeaks, or in off-diagonal positions, as cross peaks. Correlation

Figure 26 2D-IR correlation spectroscopy. (a) Real-time FTIR spectra collected during the initial stage of the UV curing of 1,6-hexandiol diacrylate (HDDA). (b) and (c) synchronous and asynchronous transient 2D-IR spectra respectively of HDDA obtained in the C=C stretching region. (Reproduced from Nakano et al.,[283] *Applied Spectroscopy*, by kind permission of the Society for Applied Spectroscopy.)

squares may be constructed by joining pairs of cross peaks through corresponding autopeaks, in order to highlight coherent spectral variations.[277] A positive sign for a cross peak shows that spectral variations at corresponding wavenumbers are changing in the same manner, e.g. they are either increasing or decreasing in intensity together; a negative sign highlights opposing changes. Sequential or unsynchronized variations are depicted in the asynchronous 2D correlation spectrum. Cross peaks in an asynchronous spectrum develop when two spectral features vary out of phase with each other. A positive sign indicates that the variation in ν_1 occurs predominantly before that of ν_2, the sign is reversed if the ν_1 change occurs after that of ν_2,[277] where ν_1 is displayed as the horizontal axis and ν_2 as the vertical axis. A simple illustratation taken from Nakano et al.[283] is shown in Figure 26. The real time FTIR spectra were collected during the initial stage of the UV curing of HDDA. The transient 2D infrared correlation synchronous plot in the C=C stretching region shows that the two peaks corresponding to the C=C stretching vibrations at 1636 cm^{-1} and 1620 cm^{-1} of the vinyl group change their intensities simultaneously, while, as expected, the asynchronous plot shows that these vinyl group changes are independent of changes in intensity of the band at 1598 cm^{-1}, assigned to the C=C stretching band of the photo-initiator, since its

radical generation and that of the vinylester chain reaction are occurring at different rates. This was a preliminary experiment in advance of studying a more complex system of the photopolymerization of a 1 : 1 mixture of acrylic and epoxy monomers, for which 2D-IR correlation analysis clearly showed that the radical-induced polymerization of HDDA progressed more rapidly than the cation-induced polymerization of the epoxy.[283]

13 PROCESS MEASUREMENTS

Quantitative mid-IR methods have been used extensively within industry for many years for both off-line (remote) and at- or near-line product quality assurance and production monitoring. Typical examples include co- and ter-polymer composition and formulation determinations, end group levels or balance for polycondensations, and residual monomer concentrations, whereas for other than specialized applications, such as film thickness gauging,[285] until recently on-line methods were a rarity. However, several advances have seen mid-infrared instrumentation become increasingly effective and utilized as a means for on- or in-line continuous measurements of polymer production processes (see article **Infrared Spectroscopy in Process Analysis** in this encyclopedia and D.W. Vidrine[286]). There has been a consolidation of multivariate data analysis techniques into the portfolio of quantitative methods commonly applied to infrared spectroscopic data. In addition, there have been important developments in sampling techniques, such as the introduction of a diverse range of sampling probes, although lack of robust, low attenuation fiber optics for the mid-infrared region still poses a major limitation. (A schematic of an immersion probe[171,287] is shown in Figure 19, see section 7.7.) Another commercial probe design uses a diamond ATR sensing head.[288] Also, spectrometers targeted for use at production environments have been increasingly marketed.

Although many mid-infrared techniques have been developed and applied to monitoring industrial processes,[289] the fine details of many process spectroscopy applications remain hidden or buried in patents or are of such propriety importance that they are never disclosed. On-line flow cell FTIR systems have been described and applied to the compositional analysis of polymer melts.[290–294] One such demonstrated the feasibility for the on-line compositional analysis of propylene/ethylene copolymer melt-streams by a process FTIR spectroscopy system coupled with PLS data analysis.[293] In another, silica and erucamide additive levels were determined in LDPE compounds extruded through the on-line analyser.[294] The potential of TIRES[34] has already been mentioned briefly, see section 3.4, and a range of possible on-line applications have been reported.[295–298]

14 MICROSPECTROSCOPY

Many analytical problems associated with polymer and rubber chemistry and technology and product satisfactions benefit from investigation with infrared micro-spectroscopy.[16,82,83,299] FTIR-microanalysis combines the attributes of light microscopy with the advantages of infrared spectroscopy. Chemical structure or physical characterization of small samples or domains selected by light microscopy may be investigated as seen by FTIR, since in an FTIR-microscope the visual and infrared optical trains are collinear and parfocal. Masks in remote image planes define the area identified for spectroscopic analysis. Their aperture size is limited practically by diffraction to a spatial resolution of ca. 10 μm. (By comparison, dispersive Raman microprobe systems are capable of better lateral spatial resolution, typically ca. 1–2 μm.) Maps of inhomogeneity or anisotropy may be built up point by point and displayed as contour or axonometric plots of functional group absorbance intensity.[300] An alternative approach, which utilizes an infrared array detector coupled with a step-scan FTIR spectrometer, allows for spectroscopic chemical imaging.[301] Probe microanalysis infrared spectra may be recorded both by transmission and reflection techniques, including internal reflection and grazing-incidence reflection–absorption.

14.1 Fourier Transform Infrared Microscopy: Sample Presentation

The same criteria that were discussed for macro-sampling in section 3.1 apply for probe micro-transmission measurements by FTIR microscopy. That is, a high spectral contrast spectrum free from optical aberrations will only be obtained from a thin, continuous, homogeneous, uniform thickness sample of an area greater than that of the defined sampling aperture; although very flat, optically transparent specimens may well suffer from some inteference fringing. Samples may be supported on an infrared transparent window mounted on the microscope sampling stage. Frequently used methods for preparing specimens include microtoming and flattening in a compression cell.

Microtoming is commonly employed to generate an appropriate thickness cross-section specimen from a multi-layered or laminate structure. The infrared microanalysis spectrum may then be recorded from each layer successively, after appropriate aperture masking. Best specimens are created using either glass or diamond

blades. Diamond cleaving knives and diamond-edge or carbide-steel micro-planes may be used for scraping off or shaving off respectively thin sections from a sample. Diamond anvil and other types of compression cells provide a very effective means to reducing the thickness of small samples, and flattening and containing them. A roller-knife, which has a polished steel wheel head, may be used to flatten some samples such as certain fibers. It may also be used sometimes successfully for transferring to its polished surface a material that is contaminating the surface of a polymer product, such as an additive bloom; the transferred material may then be characterized in situ on the roller knife by transflectance infrared microanalysis.

Reflection–absorption (transflectance) is a commonly used microanalysis approach, particularly for identifying thin coatings on metal surfaces, such as those on beverage cans. Other thin materials may be supported on a gold-coated metal disk or microscope slide. Specular reflectance microanalysis can also be a very convenient sampling procedure for some samples.[23] The area examined, however, should be essentially optically flat and the depth should be compositionally homogeneous and ''optically thick''. Microscope objectives are available which allow for grazing-incidence reflection–absorption and IRS measurement.[302] The latter is commonly known as an ATR objective; ATR is a commonly used abbreviation for an IRS measurement, mostly applied to a single internal reflection accessory. A range of ATR objective elements is available. Not all are visually transparent and do not therefore allow microscopic visual inspection of the sampling area. Ge elements are normally used with a pressure (contact) alert in order to ascertain intimate sample surface contact for ATR infrared microanalysis measurement.

14.2 Fourier Transform Infrared Microscopy Applications

FTIR microanalysis measurements fall essentially into two types – those concerned with analyzing limited amounts of sample, and those concerned with spatially resolved data. Examples of the former include contaminant analysis, laminate structure characterizations and fiber identifications. The latter may be involved with determining chemical structure gradients, such as those associated with degradation profiles, or measuring physical property anisotropy, such as molecular orientation differences through a thick film or along the axes of a polymer bottle, or determining crystallinity variations across the surface of a molding.

In the following sections some examples will be given of the wide range of analytical uses to which FTIR microscopy has been applied. Many examples of applications to polymer analysis along with discussions of sample presentation methods and criteria may be found in the study by Katon & Sommer,[303] and the guides by the ASTM[304] and Humecki.[305]

14.2.1 Fourier Transform Infrared Microscopy: Contaminant Analysis

Performance criteria and aesthetics both require that polymer and rubber products are free from contamination. FTIR microscopy is a key tool in identifying ''foreign material'' in or on the surface of commercial products. These imperfections must, of course, be of a size appropriate to FTIR microanalysis. Isolated contaminants may be mounted on a KBr window or flattened and contained in a compression cell for a transmission measurement. For a buried contaminant it may be expedient to microtome a thin section through it, so that it becomes exposed within the host material. Surface contaminants may be examined by FTIR/ATR microscopy.

14.2.2 Fourier Transform Infrared Microscopy: Defect Analysis

As with contamination analysis, characterizing the structure of visible defects is important to failure analyses and quality control. Chemical structure or form difference of localized process- or fabrication-induced defects or in-use property deterioration may often be successively determined by infrared microanalysis. The imperfections may arise typically from poor constituent dispersion in a formulation or blend, differences in molecular weight or end groups from the bulk, morphology differences, degraded, uncured or cross-linked material, all of which may often be characterized readily by FTIR microscopy examinations.

Three examples illustrating the benefits of infrared spectroscopic analysis to this type of investigation are shown in Figure 27. All three imperfections were evident as gel-like defects in bulk film; locally their visual appearances were variously described as ''nibs'', ''blobs'', ''gels'', or some similar term. Each arose from material that, because of a different rheological property, processed differently to the bulk. The first arose because of poor dispersion of a rubber component in a polymer blend.[16] In the second investigation a deficiency in an aryl–Cl end group concentration in a PES was highlighted from 100 μm spatially resolved spectra recorded from a microtomed section from a PES film.[82] The third investigation showed that the defect was associated with amorphous polymer in a matrix of crystalline PEEK.[16] The defect was isolated from the bulk sample and flattened in a diamond window micro-compression cell for infrared analysis.

Figure 27 FTIR microscopy, defect analysis. (a) Schematic of a microtomed section from a 100 μm thickness film made from a blend of a PP and an ethylene/propylene rubber, which had a poor profile, exhibiting prominences ("nibs"). Infrared transmission spectra were recorded from the areas indicated using 50 μm aperture masking. The absorbance difference spectrum generated between these spectra, shown in the figure, shows clearly that the "nibs" were a consequence of poor dispersion of the rubber phase. (b) FTIR absorbance spectra recorded from a microtomed section of a PES film, aperture 100 μm. The lower spectrum is representative of the defect area, the upper spectrum is that of the base film. The band at 760 cm^{-1} is attributable to the aryl-Cl end group. (c) FTIR absorbance spectrum recorded from a defect isolated from a PEEK polymer film and compressed in a diamond window micro-compression cell. The spectrum is close to that of amorphous PEEK. (d) Reference spectrum recorded similarly from a section of the matrix semi-crystalline PEEK polymer film.

14.2.3 Fourier Transform Infrared Microscopy: Laminate Structure Analysis

Spectroscopic fingerprinting of the layers in laminated film products is perhaps one of the most advertised and a commonly used application of FTIR microscopy in polymer analysis. The procedure requires that a thin cross-section is microtomed at right angles to the surface of the multi-layer film.[16,82,83,306] (Oblique sectioning may be used to expose wider layers.) Successive layers of the film are then examined, after appropriate remote aperture masking, by transmission FTIR microscopy. Diffraction effects usually limit the recording of "pure" layer spectra to those layers with a width of 10 μm or greater. Thinner adhesive layers may sometimes be spread wider by squeezing the section in a compression cell.[16] An illustration of an analysis of part of a multilayer sample is given in Figure 28.

Figure 28 FTIR microscopy of a 20 µm cross-section from a multilayer polymer card sample. (a) Transmission spectrum of layer 5, an ester plasticized PVC, probably filled with TiO_2; (b) transmission spectrum of layer 6, an amorphous terephthalate/isophthalate copolyester; (c) image as seen in transmitted visible light through crossed polars; (d) transmission spectrum of layer 7, a barium sulphate filled PET.

14.2.4 Fourier Transform Infrared Microscopy: Failure Surface Analysis

Surface layer defect and failure surface analysis may be accomplished with FTIR/ATR microscopy. For example, ATR microanalyses performed on failure regions resulting from a mechanical shearing test on two steel sheets bonded with a PU adhesive revealed a distinct inhomogeneity in the distribution of the hard PU segments in the soft PU segment rich matrix through the adhesive layer thickness.[307] A greater concentration of hard segments was observed in a rupture region near the adhesive/steel interface compared with that of a cohesive failure surface localized in the bulk of the adhesive layer. Evidence for this was given by the relative intensity of the νCH peaks to those of νNH and νC=O in the two failure regions, and the differences rationalized as perhaps resulting from hydrogen bonding developed between urethane groups and metallic oxides and hydroxides on the metal surface.

FTIR/ATR microscopy spectra from another multilayer film failure analysis are shown in Figure 29. The surface layer spectra from the initial delamination region (''mechanical shock induced'') show clearly that adhesive failure is taking place at the interface between the heat seal layer, as evidenced by the copolyester peak at 930 cm^{-1}. In contrast, the surface layer spectra recorded from each exposed surface from the propagated delamination region (''tension failure'') support cohesive failure, since the two spectra are essentially identical and that of PET. This diagnosis is shown schematically in Figure 29.

Figure 29 FTIR microscopy, plane of failure analysis of ID card. (a) Infrared transmission spectra of exposed surfaces at section of propagated delamination; neither of these spectra show the band at ca. 930 cm^{-1}, indicating that tension failure has continued through the PET layer, and not at the layer interface. (b) Infrared transmission spectra of exposed surfaces at initial point of delamination; the weak absorption band in the upper spectrum at ca. 930 cm^{-1} that is not present in the lower spectrum indicates that the initial delamination occurred between the PET and the copolyester heat seal layer. (c) Schematic of multilayer card structure.

14.2.5 Fourier Transform Infrared Microscopy: Fiber Analysis

It is possible to characterize fibers by FTIR/ATR microscopy; indeed, by carefully controlling the contact pressure both a thin sheath polymer layer and the polymer core of a heterofil fiber have been identified.[16] It is much more usual, however, to record transmission FTIR microscopy spectra from fiber specimens that have been flattened by either a tool like a roller-knife[308,309] or metal probe[310] or contained within a compression cell.[309,311] Such preparation procedures are, however, very likely to alter the physical characteristics of the fiber, such as level of crystallinity and degree of molecular orientation. However, if the fiber is not flattened its transmission FTIR microscopy spectrum will likely be severely distorted and of poor spectral contrast. Spectral variations will also be minimized if fibers that are oriented are mounted always in a similar direction in relation to the microscope horizontal axes.

14.2.6 Fourier Transform Infrared Microscopy: Chemical Composition Profiling and Mapping

Gradient profiling or mapping of chemical functional group intensity variations through or on the surface of a polymeric product is a widely used application for FTIR microscopy. Anisotropy may be visualized from stack plots generated from point-by-point measurements along a line profile or from axonometric or contour plots generated from normalized intensity values from consecutive point-by-point readings taken across a pre-defined area. These intensity variations may be processed and displayed as false-colour or gray-scale images to aid visualization. Point-by-point, equidistant step displacements can be achieved with an automated motorized $x-y$ microscope stage.

Figure 30 illustrates the preparation procedure for creating a specimen from an aged polymer sample. Figure 30 shows also a degradation profile generated from the illustrated stack plot obtained from examining

Figure 30 FTIR microscopy of aged polymer films. (a) Schematic showing preparation of thin microtome cross-sections. (b) Schematic representation of the analysis method. (c) Infrared absorbance spectra in the carbonyl stretching region of the first layers of a photo-oxidized PP sample. 15 μm wide sections of a PP sample irradiated in the presence of air under artificial photo-aging conditions.[312] Similar analyses have been undertaken for PVC [313–315] and PMMA.[315] The spatial resolution of an FTIR microscope has been used to monitor in a similar way the time-dependent diffusion-in profiles of a UV stabilizer into a PP plaque.[316] Automated line-scan measurements were again made on microtomed sections. The sampling aperture width was set to 26 μm, with a stage step size advancement of 26 μm of the microscope stage between recordings of spectra. Differences in polymer chain structural entities may also be located. For example, FTIR microscopy has been used to highlight differences between end group (hydroxyl and carboxyl) concentrations between the edges and centers of sections microtomed from a series of PET granules taken from various stages within a solid-phase polymerization cycle.[83,293] Significant concentration differences were observed for the two positions following the solid stage polymerization step.

In another utilization of FTIR microscopy to polymer analysis, an essentially time-profiling room temperature cure study was made of the interphase regions of a PE and Poly(vinyl Alcohol) (PVAL) fiber/epoxy matrix composites.[317] Spatially resolved spectra of dimensions ca. 20–40 μm × 80–150 μm, perpendicular and parallel to the fiber axis respectively, recorded from close to the fiber and 200 μm from the fiber axis were compared. From infrared analysis, coupled with DSC measurements, among the deductions made was that moisture from the fiber surface increased the anhydride consumption in an epoxy/anhydride matrix, but the final extent of reaction (ester production) is reduced near to the fiber. This was in contrast to an epoxy/amine matrix study, in which the final cure state was unaffected by water from the fiber surface.

14.2.7 Fourier Transform Infrared Microscopy: Physical Characteristic Profiling and Mapping

Physical property anisotropy may be mapped in similar ways to those used for profiling gradients in chemical composition. For example, localized measurements have been made by FTIR microscopy of polymer conformation and morphology through fusion welds.[318–320] Figure 31 is a schematic diagram of a hot plate pipe weld, which indicates a microtomed section taken for an analysis (200 μm for PE; 50 μm for PP) and the 188 × 50 μm FTIR microscopy analysis points.[318] In two independent but similar investigations on PE,[318,321] both of which used the intensity of the 1303 cm^{-1} band of polyethylene as an indicator of amorphous content, but which used different absorbance ratio procedures, the crystallinity in the weld region was shown to be less (by ca. 2.5%) than that in the parent pipe, and minimizing at the weld centerline, see Figure 31. In contrast, in similar experiments, the helical content of PP has been determined to increase through the weld region.[318–320]

Figure 31 FTIR microscopy of polymer welds. (a) Schematic diagram of a hot plate weld. (b) Infrared determined crystallinity profile through polyethylene weld. (c) Infrared determined helical content profile through PP weld. (Figures reproduced from Stevens[318] by kind permission of TWI, Cambridge, UK.)

Polymorph microdomains in PVdF films cast from different solvents have been characterized by FTIR microscopy.[322] Different zones for infrared analysis were selected from optical micrographs, and spectra associated with the α, β and γ forms of PVdF obtained, although the presence of all three was not determined for all the films; for example, the film cast from tetrahydrofuran (THF) appeared to be completely constituted by the α form. Polarized infrared radiation FTIR microscopy analysis of drawn extruded strands of a liquid-crystalline polyester revealed that for a thicker strand (diameter 1.52 mm) the dichroic ratio was low near the strand core, but increased markedly towards the surface.[323] For thinner strands, the molecular orientation function (dichroic ratio) increased significantly compared to that of the thicker strand, and increased with decreasing diameter. However, for the thinner strands the radial differences were small. The sections examined were microtomed in the extrusion direction to a thickness of 10 μm, from strands that had been embedded in an epoxy resin. The aperture length for the FTIR microscopy examination was 200 μm in each case, having a width of 40 μm for the narrowest strand and 80 μm for the thickest strand. FTIR microscopy dichroic ratio measurements in two transverse mutually perpendicular sections along sample geometric axes of biaxially oriented polymer products may be exploited to gain insight into molecular orientation anisotropy. FTIR microscopy molecular orientation measurements, together with molecular conformation and molecular configuration determinations, have been used to investigate PET thick film curl, and profile PET bottle wall properties.[16,82,83]

14.2.8 Fourier Transform Infrared Microscopy: Imaging Applications

As mentioned in section 14.2.6 and implied in section 14.2.7, equidistant functional group normalized absorbance intensity measurements may be used to generate maps to aid visualization of composition or property variations. These maps (images) may be presented in a variety of ways. They can be pseudo three-dimensional (axonometric) plots of normalized absorbance intensity versus $x-y$ plane distances. These can be reduced to planar line contour maps, which may essentially be gradient false-colour or gray-scale coded to better highlight features and improve contrast. These maps are generated from automated, equidistant point-by-point measurements across a pre-defined sample area step-scanned by means of a motorized microscope $x-y$ stage.[324,325] Alternatively, direct gray-scale or color infrared images may be generated from spectra recorded from a global examination of the pre-defined sample area by using an FTIR step-scan spectrometer fitted with a focal plane multichannel array detector.[326,327]

A combination of difference spectra and constant thickness normalized contour plots generated from FTIR microscopy measurements have been used to make observations on the interphase region of cured epoxy resin–glass fiber reinforced composites.[328,329] Samples thin enough for transmission measurements were prepared from single 10 μm thick glass fiber monofilaments embedded in epoxy resin; the total composite sample thickness was 12–14 μm. In Figure 32

Figure 32 (a) Schematic representation of the geometry of a mapping experiment. (b) Contour plot for the 841 cm^{-1} peak for samples prepared with as-received glass fibers. (c) Contour plot for the 842 cm^{-1} peak for samples prepared with heat-cleaned glass fibers. (d) Contour plot for the 841 cm^{-1} peak for samples prepared with glass fibers treated with γ-aminopropyl-triethoxysilane (γ-APS) coupling agent. (Figures reproduced from Arvanitopoulos and Koenig,[329] from *Applied Spectroscopy*, by kind permission of the Society for Applied Spectroscopy.)

a schematic representation is shown of the geometry used for the localized transmission mapping measurements together with example contour plots generated for NH wagging mode absorbance at ca. 841 cm^{-1}. This peak revealed a higher intensity along the fiber surface for the as-received and heat-cleaned glass fibers, but showed a lower intensity value at the interfacial region for a fiber treated with the coupling agent, γ-APS. In accord with these observations, difference spectra for which the spectrum of the bulk matrix (40 μm away from the fiber center) was subtracted from that of the fiber embedded in the matrix showed a negative feature at ca. 841 cm^{-1} for γ-APS system, whereas it was positive for the fibers not treated with the coupling agent. These suggested that the uncoated glass fiber surfaces attracted the amine curing agent of the epoxy agent, but a preferential

Figure 33 (a) Polarized optical micrograph of area of PVdF spherulites used for FTIR microspectroscopy mapping. (b) Axonometric (functional group image) plot of the CF_2 stretching vibration at 1233 cm^{-1}. (c) (i) Point FTIR microscopy absorbance spectra taken in the area of the small spherulite, and (ii) point FTIR microscopy absorbance spectra taken in the area of the large banded spherulite. (Figures reproduced from Kressler et al.,[330] from *Applied Spectroscopy*, by kind permission of the Society for Applied Spectroscopy.)

repulsion occurred in the presence of γ-APS. Other specific interaction features of the interphase regions were also observed, which were associated with the different fiber surfaces. When exposed to moisture, the lowest water uptake at the interfacial region was shown to be at the silane-treated fiber, and at a certain level water was found to catalyse a polymerization reaction at the interphase.[329]

Point-by-point mapping images have been used to characterize the morphology and phase behavior of polymers[330] and polymer blends.[330,331] Figure 33 shows the polarized optical micrograph of PVdF spherulites isothermally crystallized at 160 °C.[330] This figure shows also functional group images as axonometric and contour plots, generated by the 1233 cm^{-1} band, a characteristic of the γ-modification. The step size for mapping

Figure 34 (a) FTIR false-colour image of bilayer poly(ethylene) tube section based on absorbance intensity at 1378 cm^{-1}. (b) Absorbance spectrum associated with pixel at cross-wires.

was 25 μm. The large banded spherulite belongs to the α-modification. Characteristic single-point FTIR spectra of the two regions are shown also in Figure 33. Spatially resolved images have been generated for polymer-dispersed liquid crystal systems[332] and the time dependent concentration profiles of the liquid crystal (E7) into poly(*n*-butyl methacrylate)[333] from FTIR microscopy point-by-point mapping measurements. The diffusion images were constructed from the normalized intensity of the cyano peak (2226 cm^{-1}) of the liquid crystal,[333] whereas the carbonyl intensity of the polymer was used to differentiate matrix and droplet regions.[332] Both spatially resolved, multipoint dichroic ratio measurements around a crack and images from FTIR microscopy measurements have been combined in an assessment of molecular structure in the crack tip region of unfilled natural rubber.[334,335]

Figure 34 shows the 1378 cm^{-1} FTIR microscopy image plane recorded from a 20 μm thick cross-section microtomed from a bi-layer polyethylene tube. The image was generated from data recorded with a step-scan FTIR spectrometer fitted with a focal plane array detector.[336] The detector was a 64 × 64 mercury cadmium telluride (MCT) array detector. The image area displayed is about 450 μm × 450 μm. Also shown in the figure is a spectrum associated with a pixel (ca. 7 μm × 7 μm) from the outer layer region. The image clearly separates the two polyethylenes according to their methyl content; there is a distinct boundary between the inner and outer layers, which have methyl contents per 1000 C atoms of ca. 6 and ca. 25, respectively.

ACKNOWLEDGMENTS

I owe a huge debt of gratitude to many past and present colleagues, friends and collaborators at ICI plc and the vibrational spectroscopy community at large. They have over the last 30+ years taught, explained, inspired, demonstrated, shared experiences and discussed and debated with me on a multitude of topics related to the infrared analysis and characterization of polymers.

This article describes the application of inverse gas chromatography (IGC) to the study of synthetic and natural polymers. The word ''inverse'' is used to indicate that the component of interest is the stationary phase, either as a finely divided powder or coating, dispersed on a suitable inert support and packed into a chromatographic column. The time required for a probe molecule to pass through the column gives a measure of the molecular interactions between the probe and the polymer which can be quantified with the help of chromatographic theory. Historically, most thermodynamic studies on polymers were carried out in dilute solution, but IGC provides information on condensed phases under conditions much more similar to those under which polymers are actually used.

Using this technique, melting, glass and other solid-phase transitions can be studied and quantified. Degrees of crystallinity can be determined in an unambiguous procedure without calibration by other methods. Solubility, permeability and diffusion constants can be determined for probe molecules. IGC is also used extensively in determining the permeability of additives such as antioxidants in polymers, as well as thermodynamic quantities such as activity coefficients, heats of solution, Flory–Huggins interaction parameters (χ), and solubility parameters. Surface areas can be measured at any desired temperature by the determination of the adsorption isotherms of suitable probes. Measurements on polymer blends can yield important information on polymer–polymer interactions and can be used to predict the compatibility of the components over a wide range of temperatures. The use of finite concentration IGC provides a rapid method of determining the density of crosslinks in rubber-like polymers.

Almost any commercial gas chromatograph can be easily modified to carry out IGC experiments by procedures described in this report. The method provides a wealth of information of both fundamental and practical importance in the study of polymeric materials.

1 INTRODUCTION

Much of what is now known about the structure and chemical interactions of macromolecules comes from

Encyclopedia of Analytical Chemistry
R.A. Meyers (Ed.) Copyright © John Wiley & Sons Ltd

studies in dilute solution where the polymer molecules are more or less isolated from each other. However, in most practical applications of polymers, the polymer is highly concentrated and usually represents 90% or more of the bulk phase. Experimental techniques developed for dilute solution studies are often inapplicable under these conditions. Furthermore, there is a large and increasingly important category of polymers that are insoluble in all known solvents and hence cannot be studied at all in dilute solution.

The inverse gas chromatographic procedure (sometimes called the molecular probe technique) eliminates both of these difficulties. The polymer is studied in the solid phase under conditions which can be made to approximate conditions of use, or processing and fabrication. Furthermore, although polymers may be insoluble in solvents, virtually all small organic molecules will have measurable solubilities in solid organic polymers, even when the latter are crosslinked or highly crystalline. Hence the range of interactions which can be probed by the technique is virtually unlimited.

In view of the general availability of gas chromatographic equipment, the experimental simplicity, and the ease with which large amounts of data can be collected, IGC is becoming the method of choice for the study of thermodynamic interactions of small molecules with polymers in the solid phase. However, the method is not limited to equilibrium measurements in the bulk phase. It can also be used to measure surface areas and adsorption isotherms, glass and other solid-phase transitions in polymers, degrees of crystallinity, crosslink density and diffusion constants for small molecules in polymeric materials.

2 CONVENTIONAL GAS CHROMATOGRAPHY

Gas chromatography (GC), like any other chromatographic technique, is based on the distribution of a probe molecule between two phases. In gas–solid chromatography (GSC) the phases are gas and solid; as the injected compound is carried by the gas phase through a column filled with solid phase, partition occurs via the sorption–desorption of the solute as it travels past the solid. Superimposed upon the forward velocity is radial motion of the probe molecules caused by random diffusion throughout the stationary phase. Separation of two or more components injected simultaneously is due to their differing affinities for the stationary phase. In gas–liquid chromatography (GLC) the stationary phase is a liquid coated onto a solid support. The mathematical treatment is equivalent for GLC and GSC.

There are two mechanisms of gas–solid interaction, namely *sorption* of the solute into the *bulk* stationary phase (absorption) or on the *surface* of the stationary phase (adsorption), or a combination of both. For conventional GC, the surface adsorption term is considered to be negligible. The net volume required to move the probe molecules through the column is V_N, the total volume of gas needed minus the "dead" volume in the column, found by sending an inert probe such as methane through the column (Figure 1). V_N is equal to $(t_R - t_M) \times U_T$, where t_R is the probe retention time, t_M is the marker retention time and U_T is the flow rate of carrier gas at the temperature at which it is measured. The parameter used in further calculations is V_g, the specific retention volume, Equation (1)

$$V_g = \frac{273.16}{T} \frac{V_N}{w} \frac{760}{P_o} J_2^3 \tag{1}$$

where T (K) is the temperature of the column at which the flow rate is measured, P_o is the column outlet pressure, w is the number of grams of polymer in the column and J_2^3 is a small correction due to the pressure drop along the column equal to $(2/3)\{[(P_i/P_o)^2 - 1]/[(P_i/P_o)^3 - 1]\}$ where P_i and P_o are the inlet and outlet pressure on the column.

Usually the retention volume is obtained using the experimental peak maximum to define the retention time. In this treatment for conventional GC, only bulk adsorption is assumed, and band broadening effects and the existence of a nonlinear sorption isotherm are not considered.

Everett[1] developed the thermodynamic analysis for a binary solution of components 1 (probe) and 2 (stationary phase) in the presence of a gas which is insoluble in the solution. Assuming that the molar volume of the probe, V_1, does not vary greatly with pressure, that the gas phases are only slightly imperfect, that the system is in equilibrium, and that the solute is infinitely dilute in both phases, then the infinite dilution activity coefficient of component 1 (γ_1^∞) at temperature T and total pressure P

Figure 1 Information obtained for a probe interacting with a polymer-coated stationary phase at temperature T.

can be written as Equation (2)

$$\ln \gamma_1^{\infty} = \ln \left(\frac{n_L RT}{K V_L p_1^0} - \frac{(B_{11} - V_1) p_1^0}{RT} + \frac{(2B_{13} - V_1^{\infty}) P}{RT} \right) \quad (2)$$

where n_L is the number of moles of component 2 occupying volume V_L on the column, p_1^0 is the partial pressure of 1 in the vapor phase, R is the gas constant, B_{11} is the second virial coefficient for the probe, B_{13} is the mixed virial coefficient of the solute vapor and carrier gas, V_1^{∞} is the partial molar volume of 1 at infinite dilution, P is the total pressure and K is the equilibrium partition coefficient, defined as the ratio of concentration of solute in the stationary phase, q, to that in the gas phase, c, i.e. $K \equiv q/c$.

Mixed virial coefficients are difficult to find: if the carrier gas is used at moderate pressures (a pressure of less than 2 atm or 202.65 KN m^{-2}) the last term can be ignored. Rewriting Equation (2) in terms of the specific retention volume gives Equation (3)

$$\ln \gamma_1^{\infty} = \ln \left(\frac{273.16R}{V_g p_1^0 M_1} - \frac{p_1^0 (B_{11} - V_1)}{RT} \right) \quad (3)$$

where M_1 is the molar volume of the probe. Other thermodynamic quantities can be calculated once the activity coefficient is known, for example the excess free energy of mixing, Equation (4)

$$\Delta G_m^e = RT \ln \gamma_1^{\infty} \quad (4)$$

and the excess enthalpy of mixing, Equation (5)

$$\frac{\partial \ln \gamma_1^{\infty}}{\partial (1/T)} = \frac{\Delta H_m^e}{R} \quad (5)$$

3 INVERSE GAS CHROMATOGRAPHY

In an experiment using IGC, the species of interest is the stationary phase which is usually made up of a polymer-coated support, or finely ground polymer mixed with an inert support. A GC column can be packed with such a mixture, or coated on the inside with polymer, to give a capillary column. Some studies have been done using pure polymer in the column[2,3] and using capillary columns.[4] In work on the latter, Gray and Guillet[4] found that V_g values for polystyrene (PS) were slightly higher for the open than for the packed column, possibly because of the higher specific surface area available in the open column. In another study, Lichtenthaler et al.[5] found that the capillary system is more sensitive to carrier gas flow rate, and that the V_g values differed from those obtained using the packed column by as much as 20% for poly(isobutylene) (PIB) and poly(dimethylsiloxane) (PDMS), and even more for poly(vinylacetate) (PVAc). In both cases, the difference decreased as the temperature increased. Both studies reported that the basic disadvantage of the capillary method was the difficulty in calculating the amount of polymer present.

Most of the work discussed here concerns data obtained with columns containing a polymer-coated support. The amount of polymer can be determined from Soxhlet extraction or by calcination of both coated and uncoated support, giving the weight percent of volatile material, and hence the weight of polymer. Errors involved in using IGC to do thermodynamic calculations have been examined.[6] The largest source of error is in the determination of the amount of polymer present. It was concluded that calcination was preferred over extraction owing to the presence of extractable inorganic materials in common supports.

For the characterization of new polymers the most informative IGC data are obtained from a *retention diagram*. In this experiment the value of V_g is determined over a range of temperatures and $\log V_g$ is plotted as a function of $1/T$. An instrument designed to carry out this process automatically has been described,[7–9] and conventional GCs can be readily modified to obtain these data in a similar manner.

A typical curve for a semicrystalline polymer such as polypropylene (PP) is shown in Figure 2. The slope reversals are indicative of phase transitions. Such transitions were noted[10] as early as 1965 for polyethylene (PE) and PP, but the first comprehensive study of polymer structure using IGC was reported in 1969 by Smidsrød and Guillet[11] on poly(*N*-isopropyl acrylamide). The information obtained in such an experiment depends on the temperature region of study. In the sample retention diagram shown,[12] segment AB represents the polymer below its glass transition temperature (T_g). Retention of the probe in this region arises from condensation and adsorption onto the polymer surface, because the probe is unable to diffuse into the bulk of the polymer within the time of passage of the probe peak. The slope of this straight segment is given by $(\Delta H_v - \Delta H_a)/2.3R$, where ΔH_v is the latent heat of vaporization of the probe and ΔH_a is the enthalpy of adsorption of the probe on the polymer surface.

In a study of PS[13] Braun and Guillet examined the change in shape of the retention diagram with respect to the surface-to-volume ratio of the stationary phase. As the amount of polymer on the support decreased, reversal from normal linear behavior became less pronounced (Figure 3) and at low loadings ($\leq$0.36%) the minimum was no longer detectable. However, the data collected

Figure 2 Retention diagram for a semicrystalline polymer. T_g is the glass transition temperature. T_m is the melting temperature. Area A–C represents a nonequilibrium absorption of the probe into the bulk phase; area C–D represents equilibrium absorption of the probe molecules in the amorphous polymer phase; area D–F represents the transition that occurs in crystalline polymers – the melting process; area F–G represents the equilibrium absorption of the probe molecules in the amorphous polymer phase.

Figure 3 Effect (experimental) of loading (%) on retention diagram for *n*-hexadecane on PS. T_g is taken as the first deviation from linearity of the plot.

on an automatic molecular probe machine is sufficiently precise that in this lower concentration region, T_g can be easily determined from plots of both the first and second derivatives of the experimental plots of log V_g versus $1/T$ (see Figure 4).

The results for PS (Figure 3) showed that the temperature of first deviation from linearity remained constant (96–98 °C). This temperature is interpreted as the glass

Figure 4 (■) Overall slope and (○) derivative of (●) retention diagram for *n*-hexadecane on PS.

transition T_g. Theoretically this represents the first detectable contribution of bulk sorption to the total retention volume, attributed to the diffusion of the probe into the bulk polymer which reflects the mobility of small 20–40 carbon atom segments, leading to a large increase in its free volume. This is the temperature at which the amorphous polymer changes from the glassy to the rubber-like state. These authors also derived model calculations of retention diagrams using a simple bimodal absorption mechanism which matched the experimental curves (Figure 5).

The next region, corresponding to a change in the slope of the diagram (B–C in Figure 2), represents a nonequilibrium absorption of the probe into the bulk phase. The diffusion rate is slow in this region, hence the molecules injected as a pulse at this temperature would not penetrate through the entire bulk of the polymer during the time of passage of the solute peak. The solute does not have time to reach an equilibrium partition between polymer and carrier gas, hence the V_g value obtained is flow rate dependent. Bulk contribution to the retention volume increases up to point C, which is a

Figure 5 Model calculations of the shape of the retention diagram for a glassy polymer (such as PS) as a function of the thickness of the polymer layer (L).

function of the film thickness. This maximum temperature is reached when the increase in bulk sorption caused by the increase in the probe diffusion constant, D, is balanced by the decrease in retention caused by increased volatility of the probe. In this nonequilibrium region it is possible to obtain information about the probe diffusion coefficient, D, and its dependence on temperature. For noncrystalline polymers, normal liquid-like behavior is achieved at C. Section C–D represents equilibrium absorption of the probe molecules in the amorphous polymer phase. Contributions to V_g come from surface adsorption, bulk absorption and condensation on the surface. The surfaces available to the probe are the polymer–gas and polymer–support interface, and any additional surfaces between crystalline and amorphous regions in the bulk polymer. The slope here is given by Equation (6)

$$\frac{\Delta H_v - \sum_i b_i \Delta H_{a_i} - \Delta H_m}{2.3R} \qquad (6)$$

The b_i values are weighting factors for each surface and ΔH_a are the enthalpies of adsorption; these can be found experimentally[14] and are related to the surface-to-polymer ratio for the polymer film (ΔH_m is the enthalpy of mixing of the polymer and probe.)

The following section of the curve (D–F) represents the next transition that occurs in crystalline polymers – the melting process. Since the crystalline phase is usually impermeable, this section of the plot can give information about the size, shape and distribution of crystalline regions. The final, linear section of the plot represents the wholly amorphous polymer. Extrapolation of this line to lower temperatures and comparison of these values with the true experimental values gives information about the percentage crystallinity of the sample at any temperature, reflected by the difference in specific volume (caused by bulk sorption) between a totally amorphous and partially crystalline product. This percentage crystallinity is given by Equation (7)

$$\%\text{Crystallinity} = 1 - \frac{V_{g(\text{experimental})}}{V_{g(\text{extrapolated})}} \times 100 \qquad (7)$$

Since the use of GC data to obtain thermodynamic quantities is based on the bulk absorption model, it is only in the latter region that experimental data can be used to obtain activity coefficients, and so on.[13] To ensure that the V_g values do represent pure bulk absorption they must be independent of the carrier gas flow rate. Once this is confirmed, the presence of bulk sorption only is verified by measuring V_g for the same probe at several percentage loadings of polymer. If V_g changes, it should be extrapolated to infinite percentage loading. This step is essential before doing any thermodynamic calculations.

4 THE GLASS TRANSITION

Numerous studies have been carried out concerning the effect of experimental variables on the glass transition. Llorente et al.[15] studied poly(cyclohexyl methacrylate) using good and bad solvents as probes; both showed a transition in the retention diagram, but only the nonsolvents gave T_g in quantitative agreement with values from differential scanning calorimetry (DSC) measurements.

Studies have been reported on the glass transitions of PVAc,[16] PP, poly(1-butene), and ethylene–propylene copolymers,[17] as well as polymer blends including PS–butadiene,[18] polyacrylonitrile,[2,19] poly(ethylene terephthalate) (PET)[20] and poly(ε-caprolactam),[21] blends of poly(methyl methacrylate) (PMMA) and poly(vinyl chloride) (PVC),[22] block copolymers of styrene and tetrahydrofuran[23] and graft polymers of methyl methacrylate and stearyl methacrylate.[24] In general, compatible systems are detectable if the mixture demonstrates only a single glass transition.

Braun and Guillet[25] investigated the failure of some probes to detect T_g. They found that the solubility of a probe in the polymer was not enough to characterize the polymer–probe interaction near T_g. Interactions of the probe with both the bulk and the surface of the stationary phase must be considered. To maximize reversal in the $\ln V_g$ versus $1/T$ plot, the bulk contribution should be as large as possible and the surface term as small as possible, hence the bulk to surface ratio, not the solubility of probe in polymer, is the critical parameter.

5 SURFACE STUDIES

5.1 Adsorption Isotherms

For the case of bulk absorption, when the retention volume is independent of probe sample size, the equilibrium concentrations of the probe in the polymer and gas phase are linearly related for low concentrations of the sample.[26] When surface adsorption is present, the isotherm relating these two concentrations is often curved owing to surface heterogeneity and saturation of available sites. In addition, the experimental concentrations used may not be low enough to ensure a linear isotherm; under these conditions the shape of the isotherm can be used to investigate the adsorbate–adsorbant interaction.

There are two approaches using GC to obtain adsorption isotherms. The ''frontal'' technique takes into account kinetic factors and gas phase volume changes due to vapor adsorption. Here[27] the sample is continuously fed into the column. For substances with a Langmuir isotherm (adsorption) the result is a single sharp step, produced at the first exit of the substance. From the time needed for breakthrough, the amount of substance retained can be determined. Usually, the ''elution'' technique[28] is used, where a pulse of material is injected and the shape of the isotherm is found from a single unsymmetrical peak. Using the gas phase concentration of eluted probe vapor, c, the retention volume may be calculated,[29] Equation (8)

$$a = \frac{1}{m} \int_0^c V_c \, dc \tag{8}$$

where a is the amount of probe vapor adsorbed on mass m of adsorbant. If the only peak broadening effect present is nonlinearity of the isotherm, then one side of the elution peak should be vertical and V_c can be determined from the other, diffuse side, as in Figure 6.

Figure 6 shows the change in peak size with varying amounts of n-decane (nC$_{10}$) traveling through a column filled with PMMA-coated support.[26] As the concentration of nC$_{10}$ increases, the front profiles become more diffuse but fall on a common curve while the rear profiles remain almost vertical, fulfilling the experimental requirements needed to use the elution technique in finding the adsorption isotherm. The amount of nC$_{10}$ adsorbed on the column can be described[30] as a function of its partial pressure, p, Equation (9)

$$p = \frac{m_{cal} q R T}{S_{cal} \dot{V}} h \tag{9}$$

where h is the peak height, S_{cal} the calibration peak area on the recorder chart, m_{cal} the number of moles of nC$_{10}$, q the recorder chart speed and $\dot{V}$ the carrier gas flow rate at temperature T. The amount of nC$_{10}$ sorbed per unit

Figure 6 Chromatographic peak shapes for larger injections of decane (0.03, 0.06, 0.15, 0.3, 0.5, 0.7, 1.0 μL) on a column packed with PMMA beads.

weight of sorbant corresponding to the partial pressure p is, Equation (10)

$$a = \frac{m_{cal} S_{ads}}{m S_{cal}} \tag{10}$$

where m is the mass of sorbant and S_{ads} is the chart area bounded by the diffuse profile of the chromatogram. If different areas (S_{ads}) corresponding to different values of h are measured, the isotherm relating a and p may be found, using the above two equations.

Several polymers were investigated by Gray and Guillet[26] using nC$_{10}$ as the probe. For PMMA beads, and PS- and PVAc-coated glass beads, the isotherms represented multilayer adsorption (type II in Brunauer's classification[31]); here the heat of adsorption is equal to or less than the heat of liquification of the adsorbate. As the amount of adsorbate on the surface was increased, the partial vapor pressure approached (as a limit) the vapor pressure of pure adsorbate at T. Apparently, for nC$_{10}$ interaction with glassy polymers, the shape of the isotherm at high coverages is governed primarily by surface saturation. Using the frontal curve in Figure 6 one can construct[26] adsorption isotherms, as shown in Figure 7 at various temperatures.

For nC$_{10}$ on poly(styrene-co-divinylbenzene) beads, and on PS-coated glass beads, the peak retention times increased with decreasing sample size. The rear profiles did not fall on a common curve, implying nonequilibrium conditions and that some kinetic process (probably penetration of the probe into bulk polymer) was the cause of the peak broadening. Bulk sorption below T_g

Figure 7 Adsorption isotherms at indicated temperatures for *n*-decane on PMMA blends.

is known, but it is slower and more complex than for above T_g.[32] This explanation was substantiated by a comparison study of nC_{10} with PE (where bulk sorption is rapid) and with glass beads (no bulk sorption). For the latter case, at low concentrations of probe the rear slopes were almost superimposable, hence the factor causing peak broadening was absent; it therefore seems probable that peak tailing was due to limited bulk sorption.

5.2 Surface Areas

Usually it is assumed that bulk and surface processes make independent contributions to the retention volume (V_R),[33] Equation (11)

$$V_R = K_b w_L + K_a A_L \tag{11}$$

where K_b and K_a are the bulk and surface partition coefficients, respectively, w_L is the mass and A_L is the surface area of the stationary phase. If w_L is varied, a plot of V_R/w_L against $1/w_L$ will give an intercept of K_b and a slope of K_a/A_L. To ensure that equilibrium data are being used, the retention volumes must be extrapolated to infinite dilution of probe, zero flow rate of carrier gas, then infinite percentage loading of the column. Knowing A_L as a function of V_L, K_a can be found. This approach assumes negligible contribution from other adsorption processes. In addition, small sample sizes are used so that V_R, K_b and K_a can be assumed to be independent of sample concentration. The surface contribution is expected to be important if the vapor has low solubility (therefore low bulk concentration) in the polymer, or if there are strong dipole–dipole or hydrogen bonding interactions between the probe and the polymer. Below T_g the bulk contribution is often assumed to be negligible, leaving V_R equal to $K_a A_L$. The surface partition coefficient can therefore be found by using a support of known surface area; conversely, by comparison of retention volumes for the same polymer–probe system the surface area of the stationary phase can be found. The surface partition coefficient can be rewritten as Equation (12)

$$\ln K_a = \ln K_{a,0} - \left(\frac{\Delta H_a}{RT}\right. \tag{12}$$

where ΔH_a is the enthalpy of adsorption. If the specific retention volume, V_g, is used, the expression for the surface area is, Equation (13)

$$\ln A_L = \ln V_g + \ln w_L - \ln K_{a,0} + \left(\frac{\Delta H_a}{RT}\right. \tag{13}$$

Another expression for surface area involves the surface area of the uncoated stationary phase and the known amounts of polymer and inert support, Equation (14)

$$A_L = w_L S_{ps} \quad \frac{100}{\chi} - 1 \tag{14}$$

where χ is percentage loading of polymer on the support and S_{ps} is the accessible surface area, i.e. that covered by the polymer, as seen by the probe. From studies on PS[13] it was found that for greater than 1% loading, film thicknesses of 10^3 Å and larger were obtained; for loadings of 19%, the film thickness was 17 000 Å. Below 0.02% loading, it appeared that there was not sufficient material to give monolayer coverage; hence, even above T_g, surface contributions would have to be taken into account when dealing with very thin films.

In a study on PS by Galin and Rupprecht[34] it was found that the value of accessible surface area available to the probe decreased with its molecular weight; this was thought to be related to the relative dimensions of the probe molecules and the smallest pore size in the support. Branched PS[34] and cellulose fibers[35] have also been studied using this technique.

A third method of finding surface areas is the Brunauer–Emmett–Teller (BET) approach, which uses the experimental isotherm. A two-parameter BET equation is Equation (15)

$$\frac{p_1/p_1^0}{v(1-p_1/p_1^0)} = \frac{1}{v_m c} + \quad \frac{c-1}{v_m c} \quad \frac{p_1}{p_1^0} \tag{15}$$

where p_1^0 is the saturated vapor pressure of the solute, v the volume of the solute on the surface, v_m the volume of the solute on the surface supposing monolayer coverage, and c is a constant. Using values for v and p_1/p_1^0 from experimental data, the left side of Equation (15) is plotted against p_1/p_1^0 to give a straight line from whose slope and

intercept v_m can be calculated. Knowing the surface area covered by the probe molecule, the surface area in the column may be found. Results using this approach[26] were found to be in good agreement with geometric surface areas of PMMA beads and of polymers coated on glass beads.

An early example of the use of this technique was carried out by Tremaine and Gray[36] who calculated an adsorption isotherm from the variation of the peak maximum retention volume with sample size on cellulose. Surface areas, enthalpies and entropies of adsorption were found.

In another work[37] by these authors the retention volumes were fitted directly to a modified BET equation to find the monolayer capacity without deriving the adsorption isotherm. Surface area results agreed to within 5% of the values calculated using the adsorption isotherm. The GC method is particularly advantageous using materials like cellulose where the dry and wet polymer have very different properties. By saturating the carrier gas with water vapor (or any other vapor of interest), measurements can be obtained under conditions in which the material is used.

5.3 Surface Energy of Polymers

To quantify the interaction of solute in the gaseous form with the polymer layer, the surface energy, γ_s, may be obtained. The surface energy describes interaction caused by dispersive forces or a combination of dispersive forces with H-bonding or with dipole–dipole forces. Fowkes[38] first reported this method of characterization and determined the surface energy of several components. Generally, the contribution of all forces can be expressed as the energy of adhesion, Equation (16)

$$\gamma_a = \gamma^d + \gamma^{sp} \tag{16}$$

where γ^d is the contribution of dispersive forces and γ^{sp} is the contribution of specific interaction forces such as H-bonding, dipole–dipole, acid base, and so on. From the gas chromatographic measurements, V_g^0 is determined by using Equation (17). V_g^0 relates to the equilibrium constant K between the adsorbed solute and the polymer surface:

$$V_g^0 = K_s A \tag{17}$$

where K_s is the surface partition coefficient and A is the total surface area of the polymer powder in the chromatographic column. Thermodynamically, the molar free energy of adsorption, ΔG_1^a, of solute on the polymer layer can be related to V_g^0 by Equation (18)

$$\Delta G_1^a = -RT \ln V_g^0 + C \tag{18}$$

where C is a constant depending on A. Equation (19) relates the energy of adhesion to the free energy of adsorption:

$$RT \ln V_g^0 + C = 2Na\sqrt{\gamma_s^d \gamma_i^d} \tag{19}$$

where γ_s^d and γ_i^d are the dispersive components of the solid surface and the interactive solute phase, respectively. N is Avogadro's number and a is the area of the adsorbed molecules (solutes). In IGC experiments, a series of interactive solutes such as alkanes can be injected into the chromatographic column in order to determine the dispersive surface energy, γ_s^d. A plot of ΔG_1^a or $RT \ln V_g^0$ versus the number of carbons in the alkane series is linear and the slope of the straight lines will account for the incremental contribution of ΔG_1^a.

The molar enthalpy of adsorption can also be calculated from ΔG_1^a data directly, Equation (20)

$$\Delta H_1^a = -T^2 \frac{\delta}{\delta T} \frac{\Delta G_1^a}{T} \tag{20}$$

Combining Equations (19) and (20), the dispersive surface energy is, Equation (21)

$$\gamma_s^d = \frac{1}{4_{\gamma_{CH_2}}} \left(\frac{\Delta G_a^{CH_2}}{Na_{CH_2}} \right)^2 \tag{21}$$

where γ_{CH_2} is the surface energy of a hydrocarbon consisting only of *n*-alkanes, and a_{CH_2} is the area of one $-CH_2-$ group. Equation (21) usually tests the IGC method for obtaining the dispersive surface energy of polymers.

6 CRYSTALLINITY

The crystallinity of a polymer can be studied using X-ray, infrared (IR), calorimetry, density, and other techniques, but these methods require knowledge of the properties of a 100% crystalline polymer and involve the assumption that the variation of the chosen property is linear with the degree of crystallinity. The gas chromatographic technique only assumes nonpenetration of the probe into the crystal phase below T_m.

6.1 Degree of Crystallinity

Measurements of polymer crystallinity can be readily made using the molecular probe apparatus described in section 13. The polymer can be coated from solution onto a suitable support such as Chromosorb W. However, with many polymers the thermal history of the coating process may alter the crystallinity of the sample. In this case, cryogenic grinding of the polymer, followed by screening

to remove particles larger than about 0.1 mm, will give particles which can be blended mechanically with the support prior to packing the chromatography column.

Figure 8 shows the IGC retention diagram for linear PE using decane as a probe, acquired using an automated molecular probe instrument. The column was heated at a rate of 0.50 °C min^{-1} through the melting transition while very small samples of decane ($<1.5 \times 10^{-6}$ mol) vapor and nitrogen were injected into the helium carrier gas at intervals of approximately 2.5 min. The 1-m column contained 0.16 g of polymer coated on 60/80 mesh glass beads.[39]

Above the crystalline melting point, the 32 data points are exactly linear with a standard deviation for the slope of less than 0.2%. This gives some confidence in a linear extrapolation to lower temperatures to give $\log V_g'$, where V_g' is the expected value of the retention volume of the completely amorphous polymer at each temperature in question. Thus the percent crystallinity at any temperature below T_m is given by Equation (22)

$$\%\text{Crystallinity} = 100\left(1 - \frac{V_g}{V_g'}\right) \qquad (22)$$

where V_g' is the value for the 100% amorphous polymer obtained by extrapolation.

Figure 9[39] shows a plot of percentage crystallinity against temperature, comparing GC results with DSC results. The latter were obtained by integrating the heat of fusion curve for a sample put through the same thermal cycle as the sample used in the GC. The latent heat of crystallization of perfectly crystallized PE was assumed to be 68.5 cal g^{-1}. The small differences in the two curves could be due to PE being a thin layer coated on glass when studied by DSC and being the bulk phase when studied by GC. Retention times were found to decrease as the polymer was cooled from melt to below T_m, a reflection of the decrease in the amount of amorphous material. Although the heating rate in the DSC experiments was more than twice that used in the IGC run, the close agreement between two entirely different experiments is remarkable, and is a strong confirmation of the validity of the assumptions involved in the use of both procedures.

Figure 8 Retention diagram for decane on high-density PE.

Figure 9 Percentage crystallinity versus temperature for linear PE using DSC and the molecular probe techniques: (●) DSC data, annealed at 1.25 °C min^{-1}, heated at 1.25 °C min^{-1}; (○) molecular probe data, annealed at 1.0 °C min^{-1}, heated at 0.5 °C min^{-1}.

A further improvement in crystallinity measurements by IGC is known as curvilinear extrapolation. In a study on semicrystalline PP, Braun and Guillet[40] found that the linear extrapolation gave a crystallinity of 36% at 50 °C, while using curvilinear extrapolation the curve leveled off near 66%, which was near the value of 64% obtained from density measurements. Besides giving a more accurate extension of the curved part of the retention diagram, the applicability of this approach is less dependent on the temperature range chosen than the linear method.

Experiments can also be done using mixed support with ground-up polymer; this latter method is preferred over using the solution-coated support, as the coating procedure changes the thermal history and thus the crystallinity of the sample. In a study on PE powder Hudec[41] found that a correction was necessary to account for contributions to V_g from adsorption on the support used; when performing the experiments using support alone, it was found that the retention times for

the probes were inversely dependent on temperature and represented 10% of the net retention time for the PE-coated support using the same probes. Tetradecane was most effective as a probe for particles of less than 0.07-mm diameter. Braun and Guillet[42] also found in their study on PE that for alkane probes C_8-C_{12} particles of diameter less than 0.1 mm were most effective. Equation (22) can be approximated by Equation (23)

$$\%\text{Crystallinity} = 100\ \ 1 - \frac{t_c}{t_a} \qquad (23)$$

where t_a is the retention time expected for the totally amorphous sample from the extrapolation and t_c is the retention time obtained from the melting or cooling curve.

6.2 Rates of Crystallization

In an analogous experiment, rates of crystallization for a polymer sample can be determined by melting the polymer coating and measuring its percent crystallinity as a function of time at constant temperatures below T_m. Typical plots on high-density PE are shown in Figure 10.[39]

The plots of percentage crystallinity against log time show some curvature, possibly indicating a complex kinetic scheme; the nucleation and growth process may also change with time and the amount of crystallinity. The fact that the sample is a thin polymer film coated on glass could cause this behavior, as the surface-to-volume ratio has been shown[43] to affect polymer crystallization rates. It is possible that the glass surface can initiate or stabilize nucleation on sites at a temperature where no crystallinity is detectable.

A number of early studies helped to define the scope of the IGC crystallinity procedures. In work done on

Figure 10 Percentage isothermal crystallization at the indicated temperatures as a function of time for high-density PE.

poly(ethylene glycol) adipate[44] Lipatov and Nesterov found that the degree of crystallinity of the polymer decreased with the film thickness. This was explained by hypothesizing the formation of an adsorption polymer layer at the solid interface. The proximity of this layer to the interface would result in smaller packing density, diminishing the mobility of the polymer molecules. This effect was found to be independent of the nature of the support.

In some systems there will be a surface contribution to the retention volume below T_m, leading to a low apparent crystallinity. Courval and Gray[33] studied the interactions of hydrogen-bonding probes on low-molecular-weight poly(ethylene oxide) (PEO). They found it necessary to extrapolate the retention volumes to infinite percentage loading of polymer, where surface sorption would be negligible.

Crystallinity measurements have been made on a variety of polymers, including PP,[32] PEO,[32] and linear and branched PE,[42] and copolymers of PE with vinyl acetate (VAc) and carbon monoxide (CO).[42]

In later work, Al-Saigh and Chen[45] proposed that below T_m a second adsorption term due to solute adsorption on the surface of small crystallites needs to be considered. Since the crystalline regions in semicrystalline polymers can be very small, their surface area may be significantly larger than either that of the support or the coated polymer.

7 DIFFUSION

The ability of a small molecule to diffuse through a solid polymer phase is of great importance when considering polymers for industrial applications. The diffusion of trace contaminants into a bulk polymer, and the rate at which stabilizers migrate from containers to the food inside, are two such applications where diffusion constants for small molecules at infinite dilution in the polymer system are needed. These conditions are reproduced closely in IGC experiments, making it the preferred method for obtaining diffusion constants under actual use conditions.

In theory, a sample injection that can be represented as a delta function should give a chromatogram which can also be described as a delta function. In fact, at best, the eluted peak will be broadened to give a Gaussian. Often the peak is skewed as well. Various factors combine to produce these effects, including instrumental imperfections such as dead volume in the detector, and these can be minimized by proper design.

Nonequilibrium conditions in the column and the existence of a nonlinear adsorption isotherm will result in skewed peaks. Other peak broadening factors are

diffusion of the solute through the stationary phase perpendicular (axial) to the direction of flow, and eddy diffusion, which is a result of the flow of moving gas around the particles of the column packing. Van Deemter et al.[46] related some of these effects to the plate height of the column, H, Equation (24)

$$H = A + \frac{B}{u} + Cu \tag{24}$$

where u is the linear velocity of the carrier gas in the column and A is a constant which accounts for broadening due to instrumental factors. B/u describes the diffusional spreading of the vapor as it flows through the column where, Equation (25)

$$B = 2wD_g \tag{25}$$

D_g is the diffusion coefficient of the vapor in the gas phase and w is the eddy diffusion constant (<1).

C is a constant related to the finite amount of time needed for the gas and stationary phases to reach equilibrium. Using a simple model, C can be expressed by Equation (26)

$$C = \frac{8}{\pi^2}\frac{d_f^2}{D_1}\frac{k}{(1+k)^2} \tag{26}$$

where d_f is the thickness of the stationary phase, D_1 is the diffusion coefficient of the vapor in the stationary phase and k the partition coefficient (the experimental retention time minus the retention time for an inert marker, i.e. methane).

7.1 Determination of Diffusion Constants

To find diffusion coefficients for solutes in the polymer phase, H values are calculated from the chromatographic peak shapes using Equation (27)

$$H = \frac{l}{5.54}\left(\frac{d}{t_r}\right)^2 \tag{27}$$

where l is the column length and d the measured peak width at half-height. By choosing experimental conditions carefully (minimizing dead volume and experimental response time) one factor can be made to predominate, namely diffusion in the stationary phase.

At high flow rate, B/u will approach zero, so a plot of H against u (Equation 24) should produce a linear section with slope C.[45] The stationary phase thickness can be found using Equation (28)

$$d_f = \frac{w}{\rho}\frac{3v}{r} \tag{28}$$

where w is the weight and ρ the density of the polymer on the column, and v is the volume occupied by the stationary phase, i.e. glass beads of average radius r (for support consisting of spherical beads). Figure 11 shows experimental data of H versus u for a number of probes in low-density PE and natural rubber[47] at various temperatures. In later work, measurements were made on the diffusion of antioxidants and other solvents in molten PE. The values of D and E_a, the activation energy for diffusion, are shown in Table 1.[48]

Giddings[49] worked out an expression for C under nonequilibrium conditions for a thin film distributed evenly over a solid surface, and found that the constant in Equation (26) changed from $8/\pi^2$ to 2/3. In addition, he divided C into two terms where C_g represents the gas phase mass transfer and C_s the stationary phase mass transfer. The expression for C (Equation 26) accounts only for C_s, but for a highly loaded system (>0.9%) C_g is only 3–5% of C; for a system of 0.2% loading C_g would be 15% of C and hence would have to be subtracted from C before accurate diffusion coefficients could be calculated.[50]

Figure 11 Van Deemter curves for various columns: (1) benzene/low-density PE at 27 °C; (2) benzene/natural rubber at 27 °C; (3) benzene/low-density PE at 25 °C; (4) benzene/natural rubber at 25 °C; (5) nonane/low-density PE at 50 °C; (6) decane/natural rubber at 40 °C; (7) dodecane/natural rubber at 85 °C; (8) hexadecane/PE at 200 °C.

Table 1 Diffusion coefficients and activation energies for selected solutes in low-density PE

Solute	Temperature (°C)	Diffusion coefficient $D_\ell \times 10^8$ ($cm^2\ s^{-1}$)	Activation energy, E_a ($kcal\ mol^{-1}$)

BHA = Butylated hydroxyaniline, BHT = butylated hydroxytoluene.

Giddings revised Equation (26) to Equation (29)

$$C = \frac{2}{3}\frac{d_1^2}{D_1}\frac{k}{(1+k)^2} \tag{29}$$

Knowing C, d_f and k, the diffusion coefficient D_1 can be calculated. According to this model a decrease in D_1 should result in greater peak spread but no change in the peak maximum.

The temperature dependence of D can be determined by monitoring peak shape changes with T. Gray and Guillet[47] found that for tetradecane in PE melt, D_1 increased only ten-fold between 125 and 170 °C and hence there was little change in peak shape or maximum. For the same probe in PS melt,[51] calculated D_1 values dropped sharply as T approached T_g. The peak distortion as T approaches T_g is related to the temperature dependence of D_1. At 130 °C no peak is detectable, and the solute is eluted with the carrier gas. This total absence of peak is not uncommon, and occurs because the thick polymer layer gives poor column performance (peak spreading is large compared to retention volume). Work has also been done on the effect of diffusion on the shape of chromatographic peaks in the region of the glass transition.[51]

There are advantages to finding diffusion coefficients of solutes in polymers using IGC. Polymers, being viscous, form a stable even coating on the support and rates of diffusion through polymers are slower than through other stationary phases, so the contribution to peak spreading from diffusion is more important.

In traditional analytical GC, the peak broadening is directly related to the resolving power of the columns and as such has received extensive theoretical attention.[52–55] There are two major factors that contribute to peak broadening: diffusion of the injected solute in the carrier gas and diffusion of the solute in the stationary phase. The first factor is known as the gas-phase mutual diffusion coefficient, D_g, and the second factor is related to the liquid-phase mutual diffusion coefficient, D_L.

In IGC experiments, where a polymer is a stationary phase, D_L is the polymer–solute diffusion coefficient. A large body of data is accumulated using PIB coated on Chromosorb W as the stationary phase and linear alkanes starting from methane to undecane as solutes.[56] Munk et al.[52] varied the temperature, flow rate of the carrier gas, and column loading systematically. They were able to design a method of evaluating the peak broadening data from which both diffusion coefficients, D_g and D_L, were obtained as follows, Equation (30)

$$H = A + \frac{2\gamma D_g^\infty}{u_0} + R_f(1-R_f)u_0\left(\frac{J\gamma_L}{D_L} + \frac{\gamma_g}{D_g^0}\right. \tag{30}$$

where H is the average height equivalent to one theoretical plate which is the ratio of the length of the column to the number of theoretical plates (N), u_0 is the carrier gas flow rate measured at column outlet, J is the pressure correction factor defined in Equation (1), R_f is the retardation factor, γ, γ_L and γ_g are the tortuosities of the structural factor (L and g refer to the liquid and gas phase, respectively), A is a constant factor that is independent of the flow rate, and D_g and D_L are the diffusion coefficients of the solute in the gas and liquid phase, respectively. Thus the average height equivalent to one theoretical plate of the column depends on the solute-related parameters D_g and D_L and on the column-dependent parameters A, γ, γ_g, and γ_L. The latter parameters are the same for all solutes, but they vary from column to column. If a set of columns is prepared in a similar way, one would expect the column parameters to have similar values. Therefore, for a set of columns differing only in column loading, one would expect that the parameters A, γ, γ_g, and γ_L that depend only on the column packing will be similar for all columns. In this case γ_L will be strongly dependent on the polymer loading. The R_f value can be calculated as follows, Equation (31)

$$R_f = (V_0 - V_d)(V_r - V_d) \tag{31}$$

where V_0 is the empty volume of the chromatographic column equal to the retention time of the marker, V_r

is the retention time of the solute, and V_d is the dead volume in the column measured as the retention time of the marker.

In order to calculate both diffusion coefficients, it is necessary to correct Equation (30) for gas compressibility, Equation (32)

$$\frac{(H-A)u_0}{f} = 2\gamma D_g^0 + \left(\frac{\gamma_L}{D_L} + \frac{f\gamma_g}{D_g^0} \quad R_f(1-R_f)u_0^2\frac{J}{f} \tag{32}$$

where f in most circumstances is within a few percent of unity and is a correction for gas compressibility. It is defined as follows, Equation (33)

$$f = \left(\frac{P_i}{P_o}\right)^2 + 1 \quad \frac{J^2}{2} \tag{33}$$

where P_i and P_o are inlet and outlet pressures on the column. A plot of $[(\overline{H}-A)u_0/f]$ versus $[R_f(1-R_f)u_0^2J]$ should yield a straight line with a slope of γ_g/D_g. Plots constructed in this manner using uncoated columns yielded negligible slopes within the experimental error. Considering γ_g is negligible, then plots of $[(\overline{H}-A)u_0/f]$ versus $[R_f(1-R_f)u_0^2J/f]$ using coated columns should be linear and should yield $2\gamma D_g$ as the intercept and γ_L/D_L as the slope.

8 THERMODYNAMIC STUDIES

8.1 Activity Coefficients, Heats of Mixing and Heats of Solution

In conventional GC the infinite dilution activity coefficient is expressed in terms of, among other variables, the molecular weight of the stationary phase, M_2. This approach has been used to find M_2, but in IGC the quantity of interest is γ_1^∞. When the stationary phase is a polymer, M_2 becomes difficult to quantify, especially in the case of a polydisperse sample. In addition, γ_1^∞ is defined with respect to the mole fraction of component 1 in a binary solution of small molecules. In IGC the two components are very different, both in molecular size and concentrations present. These problems are rationalized by the use of the weight fraction infinite dilution activity coefficient. Patterson et al.[57] defined the infinite dilution activity coefficient with respect to the weight fraction of component 1 (w_1), giving, Equation (34)

$$\ln\left(\frac{a_1}{w_1}\right)^\infty = \ln\left(\frac{273.16R}{p_1^0V_gM_1} - \frac{p_1^0(B_{11}-V_1)}{RT}\right) \tag{34}$$

In this manner the activity coefficient of the probe in the polymer can be found using experimental data and pure component properties alone. Using the weight fraction activity coefficient, partial molar heats of mixing (ΔH_1^∞) can be calculated (Equation 5), equivalent to ΔH_{mix}^e. DiPaola-Baranyi et al.[58] tabulated these for alkane and butanol probes at infinite dilution in PS, poly(ethylene–carbon monoxide), PE, poly(ethylene–vinyl acetate) (P(E-VAc)), PVC, poly(1-butene), poly(methylacrylate) and poly(*N*-isopropyl acrylamide). Equation (34) does not include the correction for gas phase nonideality, but using an inert carrier gas and low column pressures, the temperature coefficient of the correction should be small. Polymer–solvent systems showed small activity coefficients $(a_1/w_1)^\infty$ and excess heats of mixing (ΔH_1^∞). Nonsolvent systems had much larger activities and heats of mixing.

Heats of solution can be calculated using Equation (35)

$$\frac{-\Delta H_s}{R} = \partial \ln \frac{V_g^0}{\partial}\left(\frac{1}{T}\right. \tag{35}$$

In a study on ethylene–vinylacetate copolymers,[59] Dincer and Bonner divided ΔH_s into contributions from dispersion, dipole and induced dipole interactions and from specific interactions such as hydrogen bonding and charge-transfer complexes, Equation (36)

$$-\Delta H_s = f(\alpha, \mu) + X \tag{36}$$

where $f(\alpha, \mu)$ is a function of the probe's polarizability (α) and dipole moment (μ). A plot was made of $-\Delta H_s$ against α for alkanes and aromatics. These points were fitted to quadratic equations, and the difference between the fitted and experimental values was interpreted as the contribution due to permanent dipole and special interactions. This was taken to be quantitatively equivalent to the enthalpy of hydrogen bonding.[60] Plots were also done of $-\Delta H_s$ against μ; the form of $f(\alpha, \mu)$ was deduced from the two plots.

The free energy of mixing, ΔG_m, can be expressed using volume fractions, Equation (37)

$$\Delta G_m = kT[N_1 \ln \phi_1 + N_2 \ln \phi_2 + \chi\phi_1\phi_2(N_1 + rN_2)] \tag{37}$$

Mixing is unfavorable for $\Delta G_m \leq 0$, therefore, Equation (38)

$$\chi_{critical} \leq \frac{1}{2} \quad 1 + \left(\frac{1}{\sqrt{r}}\right)^2 \tag{38}$$

For large molecular weights r is much larger than 1, giving $\chi_{critical}$ as approximately 0.5. Since χ is a free energy parameter, it can be separated into an enthalpic (χ_H) and an entropic (χ_S) component, Equation (39)

$$\chi = \chi_H + \chi_S \tag{39}$$

χ_H can be calculated from pure component properties using the Hildebrand–Scatchard regular solution theory for nonpolar substances,[61] Equation (40)

$$\chi_H = \frac{V_1}{RT}(\delta_1 - \delta_2)^2 \tag{40}$$

where the δ values are solubility parameters, Equation (41)

$$\delta = \left(\frac{\Delta E_{vap}}{V}\right)^{1/2} \tag{41}$$

The quantity on the right is known as the cohesive energy density and is an indication of the strength of intermolecular forces in the pure component.

Experimental studies[62–64] have shown χ_S to be of the order of 0.35 and it is sometimes left as a constant.

χ can be related to the weight fraction activity coefficient. For $\phi_2 \to 1$, Equation (42)

$$\ln\left(\frac{a_1}{w_1}\right)^{\infty} = \ln\left(\frac{v_1}{v_2}\right) + 1 - \frac{V_1}{(\overline{M}_2)_n v_2} + \chi \tag{42}$$

where v_1 and v_2 are the specific volumes of the probe and polymer, respectively.

In polymers $(M_2)_n$, the number average molecular weight is usually large enough so that the second term in the last parentheses is very small. Substituting for $\ln(a_1/w_1)^{\infty}$ gives Equation (43)

$$\chi = \ln\left(\frac{273.16Rv_2}{p_1^0 V_g V_1}\right) - \frac{p_1^0(B_{11} - V_1)}{RT} - 1 \tag{43}$$

Using Equation (43), χ can be determined directly from measurements of V_g under appropriate conditions.

Most experimental work uses the original Flory–Huggins and/or the modified approach using core volumes and segments, giving χ and/or χ^*. χ is sometimes taken to have a temperature dependence of the form of Equation (44)

$$\chi = \alpha + \frac{\beta}{T} \tag{44}$$

From the original Flory–Huggins definition, a plot of χ versus $1/T$ should give a straight line. In fact, this inverse trend is only true for part of the plot. The $\chi - T$ curve is more parabolic in shape and care should be used in doing any extrapolation of χ data.

According to Flory–Huggins theory, χ should show a composition dependence but studies[65] on PS and high-density PE with benzene and decane showed no such dependence. There is an extensive literature on this subject including studies on PIB,[66–68] PDMS,[69–72] PS, amorphous PE and PP,[73] *cis*-polyisoprene,[74] linear and branched PE,[75] poly(methyl sulfoxide),[70] and poly(ethylene glycol).[76]

8.2 Finite Concentration Gas Chromatography

Work has also been done at finite concentration using GC. It involves the use of a carrier gas with a significant concentration of probe molecule in the vapor phase. A series of articles by Condor and Purnell explain the theory and experimental set-up for these studies.[77–80] Several elution techniques can be used; all start from Equation (1) and one technique is described below.

Brockmeier et al.[73] studied PS, amorphous PE and atactic PP at both infinite and finite dilution. The latter experiments were carried out using the technique of elution-on-a-plateau. The column is equilibrated with a stream of solute gas at steady concentration c. A sample concentration infinitesimally greater or less than c is injected, yielding a Gaussian peak. The first quantity of interest is the distribution isotherm which (at pressure P) is given by Equation (45)

$$q(P) = \frac{j}{w_2}\int_0^{y_0}\left(\frac{V_g}{1} - \psi\right) dc \tag{45}$$

where y_0 is the mole fraction of solute in the gas phase at pressure P_0 in a zone of concentration c, and j is a compressibility correction which approaches J_3^2 as values were always positive and decreased with increasing temperature in a complicated manner. There was a slight composition dependence, with χ'_{23} becoming lower for the PS-rich copolymers. Patterson and Robard[81] reviewed the theory and its application to mixed stationary phases. Other studies have been carried out by Olabisi,[82] Galin and Rupprecht,[83] and others.[84,85] An apparatus for performing these studies is shown in Figure 15.

8.3 Henry's Law Constants (Solubilities)

Henry's Law describes a two-component system where one of the components (1) is in very low concentration relative to the other (2). Under this condition the solubility of 1 in 2 (i.e. X_1) can be related to the partial pressure of 1 in the vapor (p_1) by Equation (46)

$$H_1 = \frac{p_1}{X_1} \tag{46}$$

where H_1 is Henry's law constant. Liu and Prausnitz[86] expressed this in terms of the fugacity of component 1, Equation (47)

$$H_1 = \lim_{x \to 0}\left(\frac{f_1}{X_1}\right) \tag{47}$$

Assuming ideal behavior of the gas in the column, and that f_1 is proportional to the weight fraction of solute in the polymer phase, then under equilibrium conditions,

Equation (48)

$$H_1 = \frac{RT}{V_g M_1} \tag{48}$$

Infinite dilution weight fraction Henry's constants have been found for *n*-alkane solutes in long-chain alkanes[87,88] ($C_{28}H_{58}$–$C_{36}H_{74}$), for volatile solutes in PVAc,[89] for liquid low-density PE at high pressures[90] and for PE[86,91] and P(E-VAc)[86] at ambient pressures.

8.4 Solubility Parameters

Solubility parameters provide another way of quantifying the thermodynamic information obtained from an IGC experiment. Previous methods for finding δ_2 values have involved swelling or viscosity measurements, graphical methods and the group-additive method outlined by Small.[92] The IGC approach uses pure component properties and experimental data only, and gives δ_2^∞ values for solutes at infinite dilution in the solid polymer phase.

DiPaola-Baranyi and Guillet[93] related the solubility parameter for probe (δ_1) and polymer (δ_2) to several thermodynamic variables. From regular solution theory, assuming zero volume change on mixing, Equation (49)

$$\Delta\overline{H}_1^\infty = V_1(\delta_1 - \delta_2)^2 \tag{49}$$

At constant pressure this can be rewritten as Equation (50)

$$\Delta\overline{G}_1^\infty = V_1(\delta_1 - \delta_2)^2 \tag{50}$$

or, combining regular solution theory with the Flory–Huggins theory, as Equation (51)

$$\chi = \frac{V_1}{RT}(\delta_1 - \delta_2)^2\chi_s \tag{51}$$

Working with hydrocarbon probes in PMMA and PS, plots were made of $(\delta_1^2/RT - A/V_1)$ against δ_1 for $A = \Delta H_1^\infty, \Delta G_1^\infty, \chi$, respectively. The plot using χ showed the least scatter of points and gave best values of δ_2^∞, and this was the method chosen for data analysis.

In such a plot the slope would be $+2\delta_2^\infty/RT$ and the intercept would be $-\delta_2^{\infty 2}/RT - \chi_s/V_1$. A typical example is shown in Figure 12.[94] Errors quoted for the slope or intercept values are the standard deviation for slope/intercept in a least-squares plot. By definition[95] the error in the intercept would be greater than that in the slope by a factor of $[(\ {}_N\delta_1^2)\ /N]^{1/2}$, where N is the number of data points.

Figure 12 Infinite dilution solubility parameters for poly(butadiene–acrylonitrile) at 75 °C. (Δ) Polar probes; (○) nonpolar probes. δ_2'(slope) = 10.00 ± 0.29.

Infinite dilution solubility parameters have been found by this method for PS and PMMA,[93] PVAc,[96] *cis*-polyisoprene, amorphous PP and an ethylene–propylene copolymer (40% w/w ethylene),[64] and also for polychloroprene and poly(butadiene–acrylonitrile), 34% w/w acrylonitrile, *cis*-1,4 polybutadiene and P(E-VAc) (40% w/w VAc).[94] Infinite dilution solubility parameters determined in this way for a number of polymers are shown in Table 2.

Experimental δ_2' values obtained by IGC are usually at temperatures greater than 25 °C, which is the temperature that literature values are quoted for. To extrapolate the experimental χ results down to 25 °C, Equation (44) is

Table 2 Infinite dilution solubility parameters

Polymer	Temperature (°C)	δ_2^∞	Ref.
PS	193	7.6 ± 0.2	93
PMMA	100	8.5 ± 0.3	93
PVAc	135	8.5 ± 0.4	96
Ethylene–propylene rubber	73	7.18 ± 0.11	97
Polyisoprene	30	7.96 ± 0.10	97
PP	30	7.67 ± 0.16	97
Polychloroprene	75	8.83 ± 0.22	94
Poly(butadiene–acrylonitrile)	75	10.00 ± 0.29	94
P(E-VAc)	75	8.26 ± 0.17	94
cis-1,4-Polybutadiene	75	7.90 ± 0.14	94

sometimes used.

$$\chi = \alpha + \frac{\beta}{T} \tag{44}$$

The validity of this procedure can be tested by measuring χ values for a range of temperatures and constructing a χ versus $1/T$ plot. If the temperature range of interest is in the downward curved section of the plot, Equation (44) can be used with care. When T_g of the polymer is 50 °C or more below room temperature, an extrapolation is not necessary and the easiest method is to perform an experiment at 25 °C.

Note that the experimental δ_2^∞ values represent infinite dilution solubility parameters, where other values quoted arise from finite concentration solution studies. δ_2^∞ values usually fall well within the literature range for a polymer, but the exact relationship between δ and δ^∞ is still not certain.

For industrial application δ is sometimes divided into components representing different contributions to the net interaction. Hansen[97] proposed that the energy of vaporization could be divided, Equation (52)

$$\Delta E^{vap} = \Delta E_d^{vap} + \Delta E_p^{vap} + \Delta E_h^{vap} \tag{52}$$

where ΔE_d^{vap} is from polar (dipole–dipole and dipole–induced dipole) forces and ΔE_h^{vap} is from hydrogen bonding or charge-transfer complexes (specific interactions). This equation leads to Equation (53)

$$\delta^2 = \delta_d^2 + \delta_p^2 + \delta_h^2 \tag{53}$$

The nonpolar part, δ_d, can be approximated using Small's method and this is subtracted from an experimental δ to leave the polar and hydrogen bonding contributions.[62,98] There is some question about how well this division represents the forces experienced by a probe in the polymer phase. Olabisi[82] concluded that the contribution of various forces could not be equally divided, and that a different unknown proportion is involved for each polymer–probe interaction.

Lipson and Guillet[94] calculated δ_2^∞ values for polybutadiene, P(E-VAc), polychloroprene and poly(butadiene–acrylonitrile) using polar, then nonpolar, then a combination of probes, and found no difference within experimental error. A factor affecting nonpolar interactions such as α, the polarizability, is also a factor in dipole-induced dipole interactions. Dipole moments (used in calculating energies of dipole–dipole interactions) will also be a partial indication of a molecule's ability to hydrogen bond. The division of δ into nonpolar/polar/specific interactions is controversial. In addition, the magnitude of the energy contribution arising out of these interactions is questionable, since IGC experiments often involve a majority of hydrocarbon probes, the most polar usually being alcohols or ketones. The net result is an experiment where a smaller fraction of the interactions are specific or polar. For δ_2^∞ calculations the division of δ may not be as applicable as for the more qualitative industrial applications.

8.5 Hydrogen Bonding

DiPaola-Baranyi et al.[76] used IGC to investigate the thermodynamics of hydrogen bonding from heats of mixing. In a binary solution of small molecules, contributions to hydrogen bonding arise from self-association in the pure solute or solvent, and from hydrogen bonding between the two components. The correction for self-association is found by measuring the heat of mixing (ΔH_1^∞) for the compound in question at infinite dilution in a nonpolar solvent, such as hexane. When the solvent in question is a polymer, amorphous PE or PP could be used.

Alternatively, heats of solution (ΔH_s) can be used in these studies, since, Equation (54)

$$\Delta H_1^\infty = \Delta H_{vap} + \Delta H_s \tag{54}$$

ΔH_{vap} is a function of the solute and experimental temperature and not the polymer, so differences in ΔH_s for a given solute at fixed temperature will reflect changes in ΔH_1^∞.

In studying the hydrogen bonding between a small molecule (solute and polymer solvent) using ΔH_s, two corrections are needed: one accounts for the nonhydrogen-bonding interactions (dipole–dipole, dispersion) that the probe is capable of, and is estimated by subtracting ΔH_s^{model} for a model, nonhydrogen-bonding probe in the polymer from ΔH_s^{probe}. The other correction accounts for the nonhydrogen-bonding interactions that the polymer is capable of, and is estimated by measuring ΔH_s values in the polymer and then in a reference polymer (such as low-density PE). The net estimate of the enthalpy change arising from hydrogen bonding between the probe and polymer is, Equation (55)

$$\Delta H_f = (\Delta H_s^{probe} - \Delta H_s^{model})_{polymer} - (\Delta H_s^{probe} - \Delta H_s^{model})_{reference\ polymer} \tag{55}$$

The experimental data needed would be ΔH_s for the probe in the polymer, then in the reference polymer, and ΔH_s for the model in the polymer, then in the reference polymer.

Some results from this procedure[76] are given in Table 3 for stationary phases P(E-VAc) and PVC using probes chosen for their hydrogen-bonding ability. Average bond energies were found to correlate well with literature values.

Table 3 Estimates of hydrogen-bonding contribution to the heat of solution[a] at 135 °C

Hydrogen donor	Model	ΔH_f (kcal mol^{-1})	
		PVAc	P(E-VAc)
Chloroform	Carbon tetrachloride	-1.3 ± 0.2	-1.0 ± 0.3
Butyl alcohol	Butyl chloride	-1.1 ± 0.3	-0.3 ± 0.4
Cyclohexanol	Cyclohexyl chloride	-2.3 ± 0.3	-1.0 ± 0.2
Phenol	Chlorobenzene	–	-1.7 ± 0.3

9 POLYMER BLENDS

In polymer blends, the key term in the miscibility of a polymer–polymer pair is the free energy of mixing, ΔG_m, Equation (56)

$$\Delta G_m = \Delta H_m - T\Delta S_m \tag{56}$$

where ΔS_m is the combinatorial entropy of mixing and ΔH_m is the molar heat of mixing. Flory[99] attributed the combinatorial entropy of mixing to the mixing of the segments on a lattice of fixed volume. Because entropy depends on volume, an additional contribution to the entropy of mixing may be necessary in Equation (56). Sanchez and Lacombe[100] developed a theory to allow for this effect by considering that all mixtures obey the equation-of-state when appropriate reducing parameters, such as pressure and temperature, are used for volume. Other equation-of-state theories of mixtures yield a combinatorial entropy of mixing similar to that of Flory. However, the combinatorial entropy becomes very small as the molecular weight of the polymer becomes high. Therefore, in the case of high-molecular-weight polymers, only the value of ΔH_m determines the miscibility of the polymer pairs. Flory and Huggins first introduced the volume fraction term ϕ_i in their theory which described polymer solutions with a reasonable success.[100] The free energy of mixing as described by the Flory–Huggins theory is, Equation (57)

$$\Delta G_{mix} = RT(n_1 \ln \phi_1 + n_2 \ln \phi_2 + n_1\phi_2\chi_{12}) \tag{57}$$

where n_i is the number of moles of the ith component, RT has its usual meaning, and χ_{12} is a parameter which is inversely proportional to absolute temperature. χ_{12} is the same parameter introduced in Equation (37) where it is an enthalpic contact parameter. The two logarithmic terms represent the (combinatory) entropy of mixing. A second parameter that can be used as an indicator for mixing is B_{12} as a binary interaction energy parameter or excess cohesive density of the polymer–solute system. B_{12} is related to the parameter χ_{12}, as in Equation (58)

$$\frac{B_{12}}{RT} = \frac{\chi_{12}}{V_1} \tag{58}$$

Subscripts 1, 2, and 3 refer to the solute, polymer 2 and polymer 3, respectively. While the sign of the combinatorial entropy always favors mixing, it is clear that its magnitude is greatly diminished as molar volumes become very large. Since ΔS_m is small, exothermic heat of mixing is a requirement for miscibility in high-molecular-weight polymer blends. (As a result of the exothermicity principle, a number of miscible polymer blends have been identified.)[101,102] Utilizing the specific retention volume, V_g^0, the polymer–polymer interaction coefficient χ_{23} can be derived. When a polymer pair is used as a stationary (liquid) phase in a chromatographic column, subscripts 2 and 3 will be used to represent polymers 2 and 3, respectively. Subscript 1 refers to the test solute. The interaction between the two polymers is expressed in terms of the free energy of mixing ΔH_{mix} which has the same form as Equation (5), only the subscripts change to 2 and 3. The first two (entropic) terms in this equation are negligible for polymer blends. Thus, for the polymer blend to be miscible (ΔG_{mix} being negative), χ_{23} must be negative. When considering the IGC of polymer blends, the free energy of mixing must be written for a three-component system. It is usually expressed as in Equation (59)

$$\Delta G_{mix} = RT[n_1 \ln \phi_1 + n_2 \ln \phi_2 + n_3 \ln \phi_3 + n_1\phi_2\chi_{12} + n_1\phi_3\chi_{13} + n_2\phi_3\chi_{23}] \tag{59}$$

Equation (59) is generally satisfactory for nonpolar mixtures. The interaction coefficients χ are largely independent of the blend composition. The derivatives of the ΔG_{mix} are, Equation (60)

$$\left(\frac{\delta \Delta G_{mix}}{\delta n_1}\right)_{n=1,p,T} = RT\left(\ln \phi_1 + 1 - \frac{V_1}{V_2}\phi_2 - \frac{V_1}{V_3}\phi_3 + \phi_2\chi_{12} + \phi_3\chi_{13} - \frac{V_1}{V_2}\phi_2\phi_3\chi_{23}\right. \tag{60}$$

In Equation (60), v_2 should be replaced by $(w_2v_2 + w_3v_3)$ where w_2 and w_3 are the weight fractions and v_2 and v_3 are the corresponding specific volumes of the two polymers in the blend. Thus, one can easily derive Equation (61):

$$\ln \frac{273.15R(w_2v_2 + w_3v_3)}{V_g^0 V_1 P_1^0} - 1 - \frac{B_{11} - V_1}{RT}P_1^0 = \phi_2\left(\chi_{12} - \frac{V_1}{M_2v_2}\right. + \phi_3\left(\chi_{13} - \frac{V_1}{M_3V_3}\right. - \frac{V_1}{V_2}\phi_2\phi_3\chi_{23} \tag{61}$$

Usually the parameter χ'_{23} is introduced as in Equation (62)

$$\chi'_{23} = \frac{V_1}{V_2}\chi_{23} \tag{62}$$

The relation for χ_{12} is given by Equation (63)

$$\chi_{12} = \ln\frac{273.15Rv_2}{V_g^0 V_1 P_1^0} - 1 + \frac{V_1}{M_2 v_2} - \frac{B_{11} - V_1}{RT}P_1^0 \tag{63}$$

Comparison of Equations (61) and (63) suggests that to obtain χ_{23} for blends, χ_{12} and χ_{13} should also be known. Thus, three columns are usually prepared, two from homopolymers and a third from a blend. The three columns should be studied under identical conditions for column temperature, carrier gas flow rate, inlet pressure, and the same solutes should be used. This keeps all auxiliary parameters (P_1^0, T, M_2, M_3, V_1, v_2, v_3, and B_{11}) identical for the three experiments, and a combination of Equation (61) (taken twice for two homopolymers) and Equation (63) for the blend will yield Equation (64)

$$\chi_{23} = \frac{\ln\dfrac{V^0_{g,\text{blend}}}{W_2v_2 + W_3v_3} - \phi_2\ln\dfrac{V^0_{g,2}}{v_2} - \phi_3\ln\dfrac{V^0_{g,3}}{v_3}}{\phi_2\phi_3} \tag{64}$$

Here, the second subscript of V_g^0 identifies the nature of the column. From Equation (64), χ'_{23} may be calculated even for solutes for which the parameters P_1^0, B_{11}, and V_1 are not known or are known with insufficient accuracy. χ_{23} can also be related to B_{23}, Equation (65)

$$B_{23} = RT\frac{\chi'_{23}}{V_1} \tag{65}$$

B_{23} determines the miscibility of the blend with a negative value being necessary for mixing. Munk et al.[103] introduced this thermodynamic parameter for the evaluation of the miscibility of blends. B_{23} may also be evaluated directly from the experimental retention volumes and weight fractions w_i by combining Equations (64) and Equation (65)

$$B_{23} = \left(\frac{RT}{V_1\phi_2\phi_3}\right)\left(\ln\frac{V^0_{g,\text{blend}}}{W_2v_2 + W_3v_3} - \phi_2\ln\frac{V^0_{g,2}}{v_2} - \phi_3\ln\frac{V^0_{g,3}}{v_3}\right) \tag{66}$$

Munk et al.[103] showed that B_{23} values evaluated from experiments depended on the chemical nature of the solute, in contradiction to theory. To correct for this effect, a phenomenological relation suggested by Pouchley et al.[104] and developed by Al-Saigh and Munk[105] was introduced.

For a complex blend involving a semicrystalline diluent, it is possible to obtain the polymer–polymer interaction coefficient χ_{23} and the interaction energy parameter B_{23} experimentally in a different way than explained earlier. This technique involves measuring the melting point depression of a polymer mixture (blend) containing a semicrystalline polymer to quantify the heat of mixing of the polymer pair.

When crystals of the semicrystalline polymer are in equilibrium with the amorphous part of the semicrystalline polymer and the amorphous counter-polymer, the melting point of the semicrystalline polymer is lower than when the equilibrium is with the amorphous part of the semicrystalline polymer only. This is known as a melting point depression, resulting in mixing amorphous polymer with a semicrystalline polymer. In most cases, the amount the melting point is depressed depends on the weight fraction of the diluent polymer. The melting point depression can be used as an indicator for polymer blend miscibility. Most of the work performed thus far using melting point depression is based on calorimetry, and there have only been a few studies using IGC.[45] The thermodynamic analysis of polymer–polymer mixtures using melting point depression can be based on Flory–Huggins theory.[99,106] Information can only be obtained at a temperature close to the pure semicrystalline polymer melting point. However, a number of factors influence the measured melting point (perfection, size, and environment of crystals) which must be accounted for.

Equation (67) is an expression of the extent of the depression of the melting point of the semicrystalline polymer after mixing,

$$\frac{1}{T_m} - \frac{1}{T_m^0} = -R\left(\frac{\Delta H_{2u}}{V_{2u}}\right)\left(\frac{\rho_2\ln\phi_2}{M_2} + \left(\frac{\rho_2}{M_2} - \frac{\rho_3}{M_3}\right)v_3 + \left(\frac{B_{23}}{RT_m}\right)\phi_3^2\right) \tag{67}$$

where T_m and T_m^0 are the melting points of polymer 2 (semicrystalline) in the mixture and pure semicrystalline polymer, respectively. The quantity $\Delta H_{2u}/V_{2u}$ is the heat of fusion of the semicrystalline polymer per unit volume. The quantities ϕ_2, ϕ_3, ρ_2, ρ_3, M_2, and M_3 are the volume fractions, densities, and molecular weight of the semicrystalline (2) and diluent polymer (3), respectively, B_{23} is the polymer–polymer interaction energy related to the Flory–Huggins interaction parameter χ'_{23} as in Equation (68)

$$B_{23} = RT_m^0\frac{\chi_{23}}{V_3} \tag{68}$$

where V_3 is the molar volume of component 3 (the amorphous diluent polymer).

The first two terms in Equation (67) are the entropic contribution and the third term is the enthalpic contribution. If the molecular weights of the semicrystalline and the diluent polymers are high, then the entropic contribution represents less than 1 °C which would play only a minor role in the melting point depression. Therefore, the values of the first two terms can be neglected, giving Equation (69)

$$\frac{1}{T_m} - \frac{1}{T_m^0} = -\frac{V_{2u}}{\Delta H_{2u}} \frac{B_{23}}{T_m} \phi_3^2 \tag{69}$$

Rearrangement yields Equation (70)

$$\frac{T_m^0 - T_m}{T_m T_m^0} = -\frac{V_{2u}}{\Delta H_{2u}} \frac{B_{23}}{T_m} \phi_3^2 \tag{70}$$

which can be rewritten in the form of Equation (71)

$$\Delta T_m = T_m^0 - T_m = -T_m^0 \frac{V_{2u}}{\Delta H_{2u}} B_{23} \phi_3^2 \tag{71}$$

ΔT_m in Equation (71) is determined experimentally from IGC, and is used for calculating the polymer–polymer interaction energy B_{23} for semicrystalline–amorphous diluent blends.

9.1 Experimental Studies on Polymer Blends

Most of the work performed in this area has focused on polymer–polymer interaction parameters. This stemmed from the fact that knowledge of compatibility is most significant when studying polymer blends. Most measurements of χ_{23} are reported in the temperature range in which the two polymers are in a molten state; the solid state is avoided even though the possibility exists that the polymer pair can be compatible in a solid or semisolid state. Deshpande et al.[107] studied a blend of PDMS/*n*-tetracosane and di-*n*-octyl phthalate (DnOP)/*n*-tetracosane. Although these blends consist of low-molecular-weight polymers, their results indicated that IGC is useful in characterizing a mixture of low-molecular-weight polymer, and applicable to a ternary stationary phase. They calculated χ_{23} by using the Prigogine–Flory theory and showed that the interaction parameters depended on the chemical nature of the solute.

Olabisi,[82] applied IGC to a blend of several blends of poly(ε-caprolactone) and PVC at 120 °C. These experiments involved mainly low-molecular-weight oligomers ranging from 2000 to 40 000 g mol^{-1}.

Su and Patterson[108] studied a blend of PS ($M_n = 600$) with poly(vinylmethyl ether) ($M_w = 10\,000$). This mixture was found to be compatible. They avoided the difficulties associated with the high glass transition temperature of PS by selecting a PS oligomer. Polymer–polymer coefficient χ_{23} parameters were obtained in the range of −0.10 to 0.30. However, isopropyl alcohol, a poor solvent for both polymers, yielded values as high as 1.47, while chloroform yielded 0.65. However, when higher molecular weight PS was used, the blends were incompatible. The highest average value for χ_{23} was 0.42 when 30% of PS was used, and the lowest average value was 0.23 when 35% PS was used. DiPaola Baranyi et al.[109,110] and Al-Saigh and Munk[105] applied IGC to a variety of polymer blends. A blend of poly(methyl acrylate)–poly(epichlorohydrin) yielded measured values of χ_{23} that varied between −0.09 and 0.49 with an experimental error of about 0.01 (see section 5).

Values within each family of solutes were clustered together. Thus, the dependence of the interaction parameters on the chemical nature of solutes was real. The literature on the IGC of polymer blends is now extensive and beyond the scope of the present report. Much of this work is summarized in a recent review by Al-Saigh.[111]

9.2 Amorphous Plasticizer Blends

There are few studies that use IGC to characterize blends containing amorphous plasticizers. Su et al.[112] applied IGC to a blend of PVC plasticized by DnOP over a temperature range of 100–130 °C. The interaction parameters were strongly negative, indicating high compatibility. However, the interaction parameters became less negative and finally positive at 0.55 vol fraction of DnOP, suggesting a lower compatibility limit. The composition dependence of χ_{23} reflects a nonrandom solution of the solute in the stationary phase and/or nonrandom mixing of PVC/DnOP, particularly for DnOP in the limited compatibility range.

Corrective measures have recently been introduced to eliminate several instrumental and procedural artifacts. It was shown that polymer–solute and polymer–polymer interaction parameters contain other solute-dependent contributions to the free energy of mixing that are not properly accounted for by the polymer solution thermodynamic theories[105] and that the variation of polymer–polymer interaction coefficient from solute to solute is partly due to experimental error and artifacts. A series of critical and corrective procedures that yielded a considerable reduction in experimental error was developed by Card et al.[113]

In order to improve IGC data, new treatments to the polymer solution theories were developed. The reader is referred to original work by Munk et al.,[103] Prolongo and co-workers,[114,115] Shi and Schreiber,[116] Farooque and Deshpande,[117] and El Hibri and Munk.[118]

In another attempt to minimize the chemical dependence on the interaction parameters, Tan and Vancso[119] proposed an alternative route for experimentalists to

study the microstructure of polymeric mixtures using the IGC method. They applied the concept of the cluster integrals to the nonrandom partitioning of solutes in a polymeric blend. Their application yielded an equation that relates the structure factor of a blend, the nonrandom distribution of solutes in a compatible blend, and the experimental quantity obtained from the IGC experiment. This equation delineates the polymer interaction parameters in terms of the structure factor of the blend.

10 INVERSE GAS CHROMATOGRAPHY STUDIES ON NATURAL AND SYNTHETIC FIBERS

IGC is particularly useful in the study of surface interactions of fibers. In these experiments it is only necessary to pack the fibers directly in the open column. Care should be taken that the fibers are uniformly dispersed in the column and not packed in such a way as to prevent access by the carrier gas to the polymer surface. Column temperatures should not exceed the melting point of the fibers and the data are analyzed by the surface energy techniques described in sections 5.1, 5.2 and 5.3.

The IGC method is used to characterize carbon[120] and cellulose fibers,[121] high-solid melamine–alkyd formulations,[122] epoxy resins,[123–125] wood,[126] Kevlar®,[127] and PE fibers,[128,129] and eucalypti Kraft pulp fibers.[130] The surface properties of these fibers were the prime interest in these studies which include the effects of surface extractives and lignin on the surface energy,[130] comparison of surface chemical properties of chlorine-dioxide-bleached pulps with peroxides and ozone-bleached pulps and to study the influence of a latex binder,[131] the thermodynamic surface properties,[129] the properties of the skin layer of ultrahigh modulus PE fibers,[128] mapping of the surface energy levels of Kevlar® fibers,[127] solvent–epoxy interaction parameters,[123–125] solubility parameters of glass fibers,[124] the nature of interactions within pigmented melamine–alkyd coating assemblies,[122] and the dispersive component of the free energy and acid–base properties of cellulose fiber surfaces.[121] Several of these studies correlated their IGC results with those obtained by other methods such as X-ray photoelectron spectroscopy (XPS), electrical conductance, electron microscopy, thermal analysis, and surface wetting studies.

11 BIOLOGICAL MOLECULES

There are only a few applications of IGC to food compared with applications to polymeric systems. These include studies on food that can easily coat a column, such as soybean,[132,133] dehydrated foods like potato starch, egg albumin and wheat gluten,[134] food packaging,[135] pasta and others.[132,136–139] King[133] has determined the solubility parameters of soybean oil δ_2 as well as the oil–solute interaction parameters of 22 solutes which indicated complete miscibility of the solutes with the oil under conditions of infinite dilution. He compared δ_2 at 59, 79, and 123 °C with the interaction parameters, and over this temperature range the δ_2 decreased from 7.9 to 6.9 $cal^{1/2}\,cm^{-3/2}$ with decreasing temperature, a trend consistent with the loss of cohesive energy density in the liquid soybean oil. Abraham and Whiting[132] characterized soybean oil in terms of polarity and polarizability. The solubility of a variety of solutes in soybean oil was factored into components that show the compound–soybean oil interactions that favor solubility. Dispersion forces dominate and provide the largest solute–oil interaction in all cases, while ethanol is the least soluble solute in soybean oil because it is small and lacks dispersive forces in spite of the acidity of the hydrogen bond.

Dry food has also been studied using IGC.[140] Using IGC, one could predict the equilibrium moisture content of potato starch, egg albumin and wheat gluten in the entire range of water activity (0.0–0.8). The isosteric heat of sorption increases with decreasing moisture content, suggesting a physical sorption on highly active polar sites. The heat of sorption of potato starch is greater than that for proteins.

Food packaging is another application of IGC, particularly the study of aroma escaping through thermosealable polymers used to packaged food.[135] Researchers determined ''scalping'' of aroma components in polymers via IGC solubility experiments. Thermosealable polyesters appear to be the best choice to minimize aroma loss by sorption in the packaging inner layer. Sorption of aroma components was shown to be selective; limonene was preferentially sorbed in linear low-density PE. This selectivity may lead to an imbalance in the flavor and may be more important than the prevention of overall loss of aroma.

12 APPLICATIONS

Applications of IGC to polymer systems focus on the determination of partition and activity coefficients (infinite dilution[82,92,108,141–143] and finite concentration[18,24,25,57,58,68,69,74,75,107,112,144–152]), polymer–solvent or polymer–polymer interaction parameters,[153–155] enthalpy of mixing,[44,58,142,156] solubility parameters,[156–161] glass-transition and melting temperatures,[8,93,156,162–167] crystallinity of polymer phase,[33,40,156,163,168–170] solute

diffusion coefficients,[47,52,55,171–176] crosslinking studies,[177–180] liquid crystals,[8] interfacial studies,[181,182] methodology,[103,114,116,183–188] hydrogen-bonding studies,[132] acidity studies,[189] food,[131,136–138] plasticizers,[190] surfactants,[191] epoxy-resin curing,[192] paints and coatings,[193] microstructure studies,[194] and the characterization of conducting polymers.[195–197] In addition, there are several excellent reviews on IGC.[111,151,181,185,198–207]

12.1 Amorphous and Semicrystalline Polymer Blends

There has been much work done on one-component stationary phases, mostly amorphous, using IGC. Such data are useful for polymers because they measure the interactions in the regions of concentration which are the most interesting in polymer science. Patterson et al.[57] resolved the difficulty of applying the usual thermodynamic equation of GC to polymeric stationary phases by introducing activity coefficients based on weight fraction. They arrived at a relationship linking IGC parameters with Flory–Huggins parameters. Many workers cautioned that anomalous behavior frequently observed in IGC in the temperature region associated with transitions often alters the resolution of the column and makes interpretation of the retention time difficult owing to changes in peak shape. Polymers at glass transition and melting points, however, offer a wealth of information about the structures and interactions in polymer stationary phases if the retention mechanism is studied quantitatively. Braun and Guillet[13] reanalyzed the retention curves in the glass retention region. They assumed that if the bulk sorption is the only retention mechanism, specific retention volumes (V_g) should be independent of the mass of the stationary phase and carrier gas flow rate. They concluded that bulk sorption and surface absorption mechanisms are operative within polymer stationary phases near T_g. They corrected the surface absorption to eliminate the dependence of the apparent thermodynamic data on the column loading. Many authors called attention to the effects of surface absorption and the necessity of performing a careful analysis of the thermodynamic data from IGC. Other authors claimed a reasonable agreement between IGC data and data obtained by other procedures.

12.2 Comparison with Other Methods

Several IGC researchers have compared their results with those obtained using other methods. The general consensus is that IGC is capable of producing data comparable with other techniques, although there has been disagreement in individual cases. Nevertheless, where there is a general agreement of results, workers have concluded that IGC is superior in speed, selectiveness in the range of experimental conditions, versatility and accuracy. Tait and Abushihada[208] among other groups compared IGC results to those obtained by vapor sorption techniques to measure polymer–solvent interaction parameters. They concluded that the IGC method is capable of obtaining data in the region (concentration and temperature) above which vapor pressure measurements became difficult, and IGC generally required less experimental time. Al-Saigh and Munk[105] concluded that IGC is sufficiently accurate to be of great value in measuring interaction parameters at infinite solvent dilution, and that solvent dependency of the measured polymer–polymer interaction parameter is a result of weakness in the thermodynamic theories used, and not a fault of the technique itself.

Al-Saigh and Chen[45] conducted experiments in a temperature range below the melting temperature of the semicrystalline diluent. As expected, a depression of the melting point of the crystalline component had occurred. They used the melting point depression to measure the miscibility by calculating B_{23}, and applied it to a blend of poly(ethyl methacrylate) (PEMA) and semicrystalline poly(vinylidene fluoride) (PVF_2). Thermodynamic quantities were in excellent agreement with those obtained by calorimetry on the same blend. For example, the B_{23} parameter for PVF_2/PEMA using DSC was $-3.18\,cal\,mL^{-1}$,[209] compared with $-3.15\,cal\,mL^{-1}$ using IGC.

Studies show that IGC agrees well with the DSC in detecting the immiscibility of poly(isobutyl methacrylate)/styrene–acrylic acid copolymer blends.[210] IGC gave positive values of the polymer–polymer interaction parameters, while DSC showed two separate glass transition temperatures. Both methods also agreed well on the miscibility of poly(styrene-co-acrylic acid) with a series of polycarbonates, showing negative values for χ_{23} and a single glass transition temperature. Although PS is immiscible with poly(isobutyl methacrylate) owing to the absence of specific interactions, it has been shown that a blend of a random copolymer (poly(styrene-co-acrylic acid)) and a homopolymer (PMMA) can be miscible in the absence of specific interactions, provided that there is sufficient repulsion between the two comonomers.[210] Both methods, IGC and DSC, have confirmed the miscibility of a blend of poly(isobutyl methacrylate) with poly(styrene-co-acrylic acid) containing 32 mol% acrylic acid and of poly(isobutyl methacrylate-co-acrylic acid) containing 22 mol% acrylic acid with poly(styrene-co-*N*,*N*-dimethylaminoethyl methacrylate) containing 23 mol% of basic comonomer.

Djadoun and co-workers have used both IGC and DSC to study the compatibility of a variety of copolymers with homopolymer[210–212] and have reported a good agreement between the two methods. Some of their

blends showed positive interaction coefficients using IGC and two glass transition temperatures with DSC. When a blend showed a negative interaction coefficient by IGC, the DSC confirmed the miscibility by showing one single glass transition temperature.

Guillet et al. used several methods, namely IGC, X-ray, IR and DSC,[9] to study the degree of crystallinity of poly(β-hydroxybutyrate-co-β-hydroxy) copolymers. The degree of crystallinity was roughly 60%. The results of IGC were quite similar to those of X-ray diffraction analysis. They found that DSC and density measurements were inappropriate for these copolymers since it is invalid to make a prior assumption about the density and the heat of fusion of the cocrystalline phase for these copolymers. IGC, however, does not depend on assumptions about the properties of the 100% crystalline polymer.

13 EXPERIMENTAL

Virtually any gas chromatograph can, with minor modifications, be used for IGC studies of polymers. Most of the studies published by Guillet et al. were carried out using commercially available GC instruments equipped with flame detectors, whereas groups such as those of Munk and Al-Saigh prefer to work with larger columns and thermal conductivity detectors which they claim give better data on the thermodynamics of polymer blends. The much higher sensitivity of the flame detector allows studies to be carried out much closer to infinite dilution and thus avoids the need to extrapolate from finite concentrations of injected probe.

For many studies, manual injection by microsyringe is satisfactory, but it is tedious if many data points are required. For the determination of retention diagrams early studies were made with automated syringes. A simpler procedure involves the use of a Hewlett-Packard headspace injector (Model 19395A) which injects a small sample of probe vapor mixed with methane as the marker gas. This gives excellent peaks with the equivalent of less than 0.01 µL of probe. A typical procedure is given below.

The polymer was deposited from $CHCl_3$ solution onto the Chromosorb G support by the pile coating method (section 13.3) to a level of 5.33 wt%. A total of 0.864 g of polymer was packed into a 6.35-mm (OD, outer diameter) $\times$ 1.2-m copper tubing column. A column containing 0.372 g polymer at 2.99 wt% was also studied in order to confirm the invariance of specific retention volume with column loading. IGC measurements were performed on a Hewlett-Packard 5890 Series II gas chromatograph equipped with a flame ionization detector. A precision mass flow controller with a range of 0–20 mL min^{-1} was used to control the nitrogen carrier gas at a nominal flow rate of 10 mL min^{-1}. Specific retention volumes were confirmed to be independent of the carrier flow rate at low flow rates. Barometric room pressure was measured to $\pm$6.67 Pa (0.05 mmHg), and column pressures were measured with a mercury manometer. Carrier gas flow rates were measured from the end of the column with a water-jacketed soap-bubble flow meter. Injections of probe vapor at infinite dilution (equivalent to $\leq$0.01 µL of liquid), mixed with methane gas as a marker, were made from a Hewlett-Packard headspace injector (Model 19395A). Data were collected, recorded and analyzed using a Hewlett-Packard Vectra ES-12 personal computer with the associated GC software package HP 3365 Chemstation. The column temperature was continuously measured to 0.1 °C with a thermocouple interfaced to the computer. The column was equilibrated for several minutes for each temperature increment of 1 or 2 °C; the necessary equilibration time was confirmed by the invariance of the retention times with the equilibration times. Equilibration is not necessary for transition temperature determinations. In this case injections are usually made at intervals during a continuous slow heating rate of 0.5 °C min^{-1}. However, thermal equilibration is usually necessary to obtain good activity coefficient data. The retention times t_r and t_m were determined from the positions of the peak maxima and recorded in the computer.

13.1 Thermodynamic Measurement on Blends

Figure 13 shows the design of an automated inverse gas chromatograph used for thermodynamic studies of blends. With certain modifications, it uses the plumbing and circuitry for any conventional gas chromatograph. For thermodynamics studies, a thermal conductivity detector is preferred because of the ease of continuous monitoring of the flow rate, however, a flame ionization detector can be modified by adding a three-way valve for diverting the flow when the flow rate is ready to be measured. Nitrogen or helium can be used as a carrier gas, although the reader should be aware of the problem of helium diffusion through the bubble in the flow meter. The design allows for continuous monitoring of the flow rate, temperature, and inlet and outlet pressures, quantities that must be measured with great precision. The design makes it possible to control these quantities electronically by means of controllers or a personal computer, and to adjust these quantities as needed. The software allows researchers to monitor and adjust these quantities as well as to collect and calculate the chromatographic quantities needed for the determination of the thermodynamic parameters.

Continuous monitoring of carrier gas flow and gas pressure is important to limit the fluctuation in the flow

Figure 13 Inverse gas chromatograph set-up. A/D, analog/digital convertor; BM, bubble meter; FL, flow meter; HD, hood; IEEE, IEEE 488 board; IP, injection port; M, mouse; NV, needle valve; OV, oven; PC, personal computer; R, two-stage regulator; S, syringe; T_1, transducer 1; T_2, transducer 2; TC, temperature control; TD, thermal detector; TS, temperature sensor; UT, ultrathermostat; WB, water bath.

to less than 0.3% in a period of 8 h of operation. The flow rate is varied within a range of 1–30 mL min^{-1} to explore its effect on V_g^0 values.

To maintain electronic communication, precision communication boards such as an IEEE 488 are interfaced with the apparatus. To measure the flow rate in milliliters per minute, an electronic temperature insensitive mass flow meter is used. The flow meter is calibrated using a thermostated soap bubble meter equipped with a glass hood (Figure 14). Thermostating is important in order to eliminate any temperature gradient along the bubble meter. The bubble meter must be fabricated with a cap as a hood to ensure a complete helium atmosphere inside the meter. If nitrogen is used as carrier gas, such a hood is not necessary. The thermostating procedure and the hood design have proved effective in lowering the error in the carrier gas flow measurements. The pressure of the gas exiting the thermal conductivity detector is close to atmospheric and passes through a coil immersed in a water bath thermostated at room temperature. The gas then enters the soap bubble meter. The atmospheric pressure is monitored with an electronic barometer that transmits readings back to the computer. A barometric pressure transmitter is available commercially as a silicon capacitive pressure sensor which offers high accuracy and long-term stability. This type of transmitter offers an accuracy of ±0.3 mbar per year. It sends a linear 0–5 V DC output signal to the data acquisition system. If electronic instruments for pressure measurements are not available, the inlet and outlet pressures should be monitored frequently using a precision mercury manometer. The outlet pressure is generally atmospheric while the inlet pressure is in the range of 900 mmHg in conventional IGC experiments.

Temperature control is a critical factor in IGC experiments. Conventional chromatographs often do not provide sufficient precision in temperature control over 8 h of operation to be of value in IGC experiments. It is important to interface a precision electronic thermometer with 0.01 °C accuracy. Fluctuation of more than 3% in temperature measurements may create a considerable error in V_g^0.

In IGC experiments, markers such as methane or air are used to account for the dead volume in a column. For the thermal conductivity detector, air or nitrogen are often used as a marker, but for a flame ionization detector, methane is the least noninteractive solute that can be used.

13.2 Column Preparation

Each sample must be weighed carefully and dissolved in the appropriate solvent (about 100 mL). The polymer

Figure 14 Flow meter is calibrated using a thermostated soap bubble meter equipped with a glass hood. A = soap solution reservoir; B = incoming helium gas from the column; C = inlet valve for fast flushing by helium gas; D = thermostated bubble meter; E = ground joint; F = inverted U-tube 1/8 in ID.

solution can then be used to coat the solid support using the pile method. The loading of the polymer sample can be calculated relative to the weight of the solid support (wt%). Chromosorb W with 60/80 mesh is often treated with dimethylchlorosilane to deactivate the hydroxyl groups on the surface. Teflon™ powder is often used when the solid polymer particles are simply blended with the support.

A typical loading in a chromatographic column varies between about 3 and 10%.

13.3 Coating the Support: the Pile Method

In this method the polymer is dissolved in a solvent. The support is piled on a watch glass and a small amount of the solution is applied on the top of the support pile. Care is taken to wet the pile as much as possible without letting the solution touch the surface of the dish, either around or under the pile. The solvent is allowed to evaporate and the pile is thoroughly mixed. Then the next portion of the solution is applied and the whole procedure is repeated until all of the solution (including several rinsings of the solution flask) is consumed. It takes typically 10–20 applications and requires only a few hours. No polymer is left on the surface of the dish. Then the support is dried in an oven and quantitatively transferred into the column.

13.4 Determination of Degree of Crosslinking of Polymer Networks

A particularly valuable application of IGC is the determination of crosslink density in rubbers and other crosslinked polymers. Its simplicity and rapidity make it useful in industrial quality control and similar applications. It involves the use of finite concentration IGC as described in section 8.2.

13.4.1 Theory

The full treatment of the elution-on-a-plateau method has been given by Conder and Purnell[77–80] and by Price and Guillet.[214] It involves the equilibration of the polymer with a stream of inert carrier gas that contains a known concentration of solvent vapor. The retention volume, V_N, of a small amount of solvent injected into the stream is then measured from Equation (72)

$$V_N = (t_r - t_m)F \tag{72}$$

where t_r and t_m are the times taken for the solvent and an inert marker to traverse the column and F is the flow rate of carrier corrected to standard conditions. Under these conditions, it may be shown that the partition isotherm for the solvent between the vapor and solution phases is given by Equation (73)

$$\frac{\partial q}{\partial c} = \frac{jV_N}{v_p}(1 - \psi) \tag{73}$$

In Equation (73), q and c are the concentrations of solvent in the liquid and vapor phases, respectively, and v_p is the volume of polymer in the column. ψ is the mole fraction of solvent in the vapor stream, corrected by the factor j for gas-phase nonideality and compressibility effects from the pressure gradient along the column.

Integration of Equation (73) and introduction of the weight of polymer in the column, w, allow calculation of the concentration of solvent in the liquid phase, q, expressed as moles per gram of polymer, Equation (74)

$$q = \frac{j}{w} \int_0^c \frac{V_N}{1 - \psi}\, dc \tag{74}$$

The concentration in the vapor stream may be calculated from the first terms of a virial expansion, Equation (75)

$$c = \frac{\psi P_A}{jRT + \psi^2 B_{11} P_A} \tag{75}$$

where P_A is the total pressure of carrier gas at the column outlet and B_{11} is the second virial coefficient of the solvent vapor at the column temperature T.

From the definition of q given above, the weight fraction of solvent in the solution phase, W_1, is, Equation (76)

$$W_1 = \frac{qM_1}{1 + qM_1} \tag{76}$$

where M_1 is the molecular weight of the solvent (probe). The activity of the solvent in solution may be calculated from the partial pressure of solvent in the carrier stream, P_1, and the saturated vapor pressure of the solvent, P_1^0. Hence, the activity coefficient Ω_1 may be found, Equation (77)

$$\Omega_1 = \frac{a_1}{W_1} = \frac{P_1}{P_1^0} W_1 \tag{77}$$

The weight fraction of solvent in the liquid phase can be calculated from Equation (76) and converted to a volume fraction by using the densities ρ, Equation (78)

$$\phi_1 = \left\{ \frac{W_1/\rho_1}{(W_1/\rho_1)(W_2/\rho_2)} \right\} \tag{78}$$

The Flory–Huggins interaction parameter is then calculated from Equation (79)

$$\chi = \left\{ \frac{\ln a_1 - \ln \phi_1 - [1 - (1/r)]\phi_2}{\phi_2^2} \right\} \tag{79}$$

the size ratio being calculated from the ratio of the molar volumes of the polymer and solvent.

13.4.2 Experimental

The apparatus used is shown schematically in Figure 15.[178]

A known partial pressure of the solvent probe *n*-hexane was introduced into the helium carrier gas by a saturator consisting of a flask containing *n*-hexane near its boiling point and a condenser through which thermostated water was passed. The partial pressure of hexane in the carrier gas was controlled by changing the temperature of the water in the saturator condenser.

The carrier gas passed over the polymer packing contained in one-quarter-inch (6.25-mm) copper columns as in conventional GC, then to a thermal conductivity detector, and finally, via a cold trap, to a soap bubble flow meter for accurate measurement of the carrier flow rate. The columns were contained in an oil bath maintained at $77.0 \pm 0.02\,^{\circ}C$.

Figure 15 Schematic diagram of finite concentration GC apparatus.

After equilibration of the detector at a known concentration of solvent vapor, the retention times of air (the inert marker) and solvent were recorded. An average of at least three values agreeing within 1% was taken. Injections of 0.1–0.5 μL were needed to give an adequate signal.

Since the saturated vapor pressure of the solvent is required for the calculation of results, solvent purity is of great importance. The *n*-hexane used was a BDH Assured grade of certified purity > 99.5%. The polymer used was an Aldrich ethylene–propylene rubber copolymer of low average molecular weight and an ethylene content of 70%.

Coating the polymer onto a solid support of 30–45 mesh size Chromosorb P was carried out in the usual manner employing hot toluene as the solvent. The percentage loading was determined by duplicate calcination to be 8.8% after correction for volatiles in the uncoated solid support.

Approximately 50 g of the polymer-coated support was placed in Pyrex glass ampules, and these were evacuated on a glass-vacuum line to a pressure of $<10^{-5}$ Torr for 2 days to degas the polymers thoroughly. The ampoules were then sealed and placed in a ^{60}Co γ-ray source (Gammacell, Atomic Energy of Canada Ltd.). The approximate dose rates were estimated from the activity and known decay rates of the source supplied by the manufacturer. After irradiation, the ampoules were opened and the packing was loaded into columns.

In this experiment, three columns were prepared with the same amounts of polymer, sample A irradiated with 140 Mrad, sample B at 200 Mrad, and sample C (unirradiated).

A plot of χ versus concentration for the uncrosslinked polymer showed a linear variation of χ with volume fraction. Linear regression of the results leads to Equation (80) for χ:

$$\chi = 0.344 + 0.004\phi_1 \tag{80}$$

For the crosslinked samples, the effective number of crosslinks was calculated from the rearranged Flory–Rehner equation, Equation (81)

$$v_e = v_2 \left\{ \frac{\ln a_1 - \ln \phi_1 - [1 - (1/r)]\phi_2 - \chi\phi_2^2}{V_1[\phi_2^{1/3} - (\phi_2/2)]} \right\} \tag{81}$$

and the value of χ determined by Equation (79). If the Flory–Rehner equation were to hold accurately, v_e should be independent of concentration. However,

Figure 16 clearly shows that the value of v_e increases with concentration but rapidly reaches a plateau. The explanation for this behavior is that v_e cannot be determined until the network is fully swollen. The values of v_e and the molecular weight between crosslinks M_c taken from the graphs are shown in Table 4. The experimental error of the results is estimated to be 5–8%.

It is clear from these data that in the routine measurement of crosslink density it is only necessary to measure two retention times, namely V_n^0 and V_n^p, where V_n^0 is the retention time at zero concentration of hexane (probe) in the carrier gas and V_n^p is the retention time at a probe concentration above that at which the polymer sample is fully swollen. Since the latter concentration can be determined experimentally as shown in Figure 16, the procedure could result in a rapid method for the determination of crosslink density in polymer samples by IGC.

Although there is some debate about the theoretical aspects of the Flory–Rehner equation, it is still the basis of the most commonly used experiments to determine crosslink density in polymers. In has been shown[180] that the IGC procedure with crosslinked PDMSs gave results similar to those obtained from classical swelling measurements, but consistently about 30% higher in crosslink density. Further research on this useful technique should lead to an improved theory to account for these differences.

Figure 16 Plot of apparent crosslink density versus concentration for irradiated ethylene–propylene rubber samples.

Table 4 Degree of crosslinking for ethylene–propylene rubber from finite concentration results

Sample	Radiation dose (Mrad)	$10^4 v_e$	M_c
A	140	4.5	2500
B	200	8.3	1205

ABBREVIATIONS AND ACRONYMS

BET	Brunauer–Emmett–Teller
DnOP	Di-*n*-octyl Phthalate
DSC	Differential Scanning Calorimetry
GC	Gas Chromatography
GLC	Gas–Liquid Chromatography
GSC	Gas–Solid Chromatography
IGC	Inverse Gas Chromatography
IR	Infrared
OD	Outer Diameter
PDMS	Poly(dimethylsiloxane)
PE	Polyethylene
PEMA	Poly(ethyl methacrylate)
PEO	Poly(ethylene oxide)
PET	Poly(ethylene terephthalate)
P(E-VAc)	Poly(ethylene–vinyl acetate)
PIB	Poly(isobutylene)
PMMA	Poly(methyl methacrylate)
PP	Polypropylene
PS	Polystyrene
PVAc	Poly(vinylacetate)
PVC	Poly(vinyl chloride)
PVF_2	Poly(vinylidene fluoride)
VAc	Vinyl Acetate
XPS	X-ray Photoelectron Spectroscopy

One major focus of this article is on models and testing techniques that can be applied readily to the research and development of polymers and rubbers. The article is divided into five sections, with the introduction being the first section. Sections 2 and 3 deal with stress–strain relationships and time- and temperature-dependent behavior. The linear Hooke's law is described first, followed by the molecular mechanism of rubber elasticity, the Mooney–Rivlin model, and the Ogden model. Three viscoelastic models are presented, together with the Boltzmann superposition principle. Various types of apparatus for viscoelastic property measurements are described. The Williams–Landel–Ferry (WLF) equation for time–temperature superposition is illustrated with experimental data.

Section 4 covers the ultimate properties. Topics include: cold drawing in crystalline polymers; temperature and pressure effects on yield stress; brittle–ductile transition; crazing; fracture; tearing of rubbers: extension of Griffith theory; viscoelastic rupture of elastomers; fatigue; and the effects of molecular weight and crystallinity. The ultimate properties are more complex and less well understood. Emphasis is placed on the most important aspects and techniques for understanding and representing yielding and fracture.

Section 5 is devoted to polymer blends and composites. Rubber-toughened polymers are used to discuss the enhancement of the deformation mechanisms in polymers. A general, mechanistic model is then presented to determine the moduli, break strengths, and break strains for polymer films containing liquid and solid microfillers.

1 INTRODUCTION

The emergence of synthetic polymers with their manifold uses has affected modern life so profoundly that our world is hardly imaginable without them. Polymers can encompass a wide range of material properties, of which hardness, deformability, toughness, and ultimate strength are amongst the most significant. Certain features, such as high modulus and impact strength, combined with low creep characteristics are desirable in a polymer if eventually it is to be subjected to loading. Unfortunately these are conflicting properties, because a polymer with a high modulus and a low creep response does not absorb energy by deforming easily, and hence has poor impact strength. This means that a compromise must be sought, depending on the application that the polymer is intended for, and this compromise requires knowledge of the mechanical response and properties in detail.

The practical utility of a polymer depends, to a great extent, on its mechanical attributes. For this reason,

Encyclopedia of Analytical Chemistry

the mechanical properties may be considered the most important of all the physical and chemical properties of high polymers for most applications. Thus, everyone working with such materials needs at least an elementary knowledge of their mechanical behavior and how this behavior can be modified by the numerous structural factors that can be varied in polymers.

The detail and in-depth discussion necessary for a thorough understanding of the mechanical properties of polymers and rubbers cannot be covered fully in the few pages of this article. The major goal is to present a concise review of various key aspects of the topic. Emphasis is placed upon general principles and useful empirical generalizations. One major focus is models and testing techniques that can be applied readily to the research and development of polymers and rubbers. Mathematical derivations are, for the most part, avoided, with only the final practical equations listed and numerous illustrative examples given. Extensive references to published literature enable the reader to find, easily and quickly, important sources of information on numerous topics.

An entire section is devoted to polymer blends and composites. The understanding of the mechanical properties of these materials is becoming more critical due to their increasing utility in structural applications and due to the complicated nature of nonlinear and synergistic effects of the phases in blend/composites in controlling their mechanical performance. The introduction of blends and composites has brought a new dimension to the applications of polymers as major load-bearing components, such as aircraft fuselages, as well as new challenges and higher expectations on understanding and predicting the mechanical properties of these materials. It has been reported[(1)] that nearly 5 million tons of thermoset composites representing a global business worth some $120 billion were used worldwide in 1997 in applications as diverse as bridges, cars, and windmills. A firm understanding of the physical properties of each polymer phase and the synergistic interactions of the different phases in blends and composites is essential in engineering design with these materials.

In the next section, the concepts of stress and strain are introduced, followed by descriptions of one-dimensional and three-dimensional Hooke's laws. The nonlinear deformation behavior of rubbers is then discussed, including the Mooney–Rivlin model and the Ogden model, which have been validated experimentally and widely used in constitutive modeling of rubber materials. The entropy-controlled molecular mechanism responsible for rubber elasticity is discussed and compared with that of metals.

Section 3 deals with the time- and temperature-dependent behavior of polymers. Three viscoelastic models (Maxwell model, Voigt model, and standard linear solid model) are presented first. The Boltzmann superposition principle is then discussed. A large portion of this section is devoted to various experiments and apparatus for viscoelastic property measurements, such as the storage and lost moduli and phase angles. Test equipment discussed includes creep and relaxation transient measurements, torsional pendulum, vibration reed, and forced vibration. The applicable frequency ranges of these tests are outlined. The WLF equation for time–temperature superposition is illustrated with experimental data.

The ultimate properties of polymers and rubbers are the subject of section 4. Various terminologies are first defined with the use of a general stress–strain diagram. Topics include: cold drawing in crystalline polymers; temperature and pressure effects on yield stress; brittle–ductile transition; crazing; fracture; tearing of rubbers: extension of Griffith theory; viscoelastic rupture of elastomers; fatigue; and the effects of molecular weight and crystallinity. The ultimate properties are more complex and less well understood. Emphasis is placed on the most important aspects and techniques for understanding and representing yielding and fracture.

Polymer blends and composites are discussed in section 5. Classifications of polymer blends and composites are given. Rubber-toughened polymers (high-impact polystyrene (HIPS) and rubber-toughened poly(methyl methacrylate) (RTPMMA)) are used as examples to discuss two enhancements of the deformation mechanisms in polymers: extensive shear yielding and crazing. A general, mechanistic model is then presented to determine the moduli, break strengths, and break strains for polymer films containing liquid and solid microfillers. This model, which is based on rigorous continuum mechanics principles, considers the filler–filler interactions, incorporates the nonlinear synergistic effects of fillers, and provides accurate predictions in comparison with experimental data.

2 STRESS AND STRAIN RELATIONSHIP

2.1 Hooke's Law

Forces applied to solids cause deformation. If we pull a rubber band, it stretches. If we compress a cylinder, it shrinks. If we bend a rod, it bends. If we twist a shaft, it twists. Tensile force causes tensile strain. Shear stress causes shear strain. To express these phenomena quantitatively, it is necessary to define strain measures, and the relationships between stress and strain.

Let an isotropic polymer solid bar with an initial length L_0 be subjected to an axial force P as shown in Figure 1.

Figure 1 A tensile bar under load.

The axial stress is equal to the force per unit area, according to Equation (1):

$$\sigma_x = \frac{P}{A_0} \tag{1}$$

where A_0 is the cross-sectional area of the bar. If the bar is stretched to a length L, it is natural to describe the change by a dimensionless ratio called strain, according to Equation (2):

$$\varepsilon_x = \frac{(L - L_0)}{L_0} = \frac{\Delta L}{L_0} \tag{2}$$

where ε_x denotes the strain in the x-direction and ΔL is the change of length under the force P. In a similar manner, the strain along the diameter of the bar is as shown in Equation (3):

$$\varepsilon_y = \varepsilon_z = \frac{(D - D_0)}{D_0} = \frac{\Delta D}{D_0} \tag{3}$$

where D is the deformed diameter, D_0 is the initial diameter, and $\Delta D = D - D_0$. This transverse strain is negative as the bar becomes thinner when stretched in the length direction.

The experimental results can be presented as a curve of the tensile stress σ_x plotted against the strain ε_x (Figure 1). It was found that, for most engineering materials subjected to an infinitesimal strain, a linear relation between the stress and strain holds, according to Equation (4):

$$\sigma_x = E\varepsilon_x \tag{4}$$

where E is a material constant called Young's modulus. Equation (4) is called Hooke's law. For an isotropic elastic material, two material constants are needed to characterize the stress–strain relationship: Young's modulus, which is the slope of the σ_x versus ε_x line in Figure 1; and Poisson's ratio, as shown in Equation (5):

$$\nu = -\frac{\text{Transverse strain}}{\text{Longitudinal strain}} = -\frac{\varepsilon_y}{\varepsilon_x} \tag{5}$$

Hence, the slope of ε_y versus ε_x is $-\nu$. Because ε_y is negative, ν is positive. Substituting $\varepsilon_x = -\varepsilon_y/\nu$ from Equation (5) into $E = \sigma_x/\varepsilon_x$ gives Equation (6):

$$\varepsilon_y = -\frac{\nu\sigma_x}{E} \tag{6}$$

To illustrate shear deformation, consider a rectangular block subjected to a balanced pair of forces F (Figure 2). If the base of the solid is fixed, the transverse force F applied causes a distortion, as shown in Figure 2. In this case the angle α can be taken as a strain measure. For a Hookean material, we have (Equation 7):

$$\tau = \frac{F}{A_0} = G\tan\alpha \approx G\alpha = G\gamma \tag{7}$$

where G is the shear modulus, γ is the shear strain, τ is the shear stress, and A_0 is the cross-sectional area of the block.

When a hydrostatic pressure $-p$ is applied to a solid of volume V_0, causing a change in volume ΔV, a bulk modulus K can be defined according to Equation (8):

$$K = \frac{-p}{(\Delta V/V_0)} \tag{8}$$

The four material constants $E, \nu, G,$ and K can be related to each other in a simple manner (Equation 9)

Figure 2 A block under shear.

Table 1 Relation among material constants in isotropic materials

Constants involved	E (Pa)	ν, Dimensionless	G (Pa)	K (Pa)
E, ν, G	$E = 2G(1+\nu)$	$\nu = \dfrac{E-2G}{2G}$	$G = \dfrac{E}{2(1+\nu)}$	
E, ν, K	$E = 3K(1-2\nu)$	$\nu = \dfrac{3K-E}{6K}$		$K = \dfrac{E}{3(1-2\nu)}$
E, G, K	$E = \dfrac{9GK}{3K+G}$		$G = \dfrac{3EK}{9K-E}$	$K = \dfrac{GE}{3(3G-E)}$
ν, G, K		$\nu = \dfrac{3K-2G}{2(3K+G)}$	$G = \dfrac{3K(1-2\nu)}{2(1+\nu)}$	$K = \dfrac{2G(1+\nu)}{3(1-2\nu)}$

because an isotropic solid has only two independent material constants. For example, we have:

$$K = \frac{E}{3(1-2\nu)} \qquad G = \frac{E}{2(1+\nu)} \tag{9}$$

For reference, Table 1 gives all possible equations relating the four constants E, ν, G, and K.

Now consider the general state of stress at a point, as illustrated in Figure 3. A complete description consists of normal stress in three directions, σ_x, σ_y, σ_z, and shear stresses on three planes, τ_{xy}, τ_{xz}, and τ_{yz}. The normal stress is considered first. If it is assumed that small strain theory applies, the strain caused by each component of stress can simply be added together. A stress in the x-direction causes a strain in the x-direction of σ_x/E. This σ_x also causes a strain in the y-direction (from Equation 6) of $-\nu\sigma_x/E$ and the same strain in the z-direction. Similarly, stresses in the y- and z-directions each cause strain in all three directions.

The situation can be summarized in Table 2. Adding the columns in this table to obtain the total strain in each direction gives Equation (10):

$$\varepsilon_x = \frac{1}{E}[\sigma_x - \nu(\sigma_y + \sigma_z)] \quad \varepsilon_y = \frac{1}{E}[\sigma_y - \nu(\sigma_x + \sigma_z)]$$
$$\varepsilon_z = \frac{1}{E}[\sigma_z - \nu(\sigma_x + \sigma_y)] \tag{10}$$

The shear strains that occur on the orthogonal planes are each related to the corresponding shear stress by the shear modulus G, according to Equation (11):

$$\gamma_{xy} = \frac{\tau_{xy}}{G} \quad \gamma_{xz} = \frac{\tau_{xz}}{G} \quad \gamma_{yz} = \frac{\tau_{yz}}{G} \tag{11}$$

Note that the shear strain on a given plane is unaffected by the shear stresses on other planes. Hence, for shear strain, there is no effect analogous to Poisson contraction. Equations (10) and (11) are called the generalized Hooke's law.

Figure 3 The six components needed to describe the state of stress.

Table 2 Stress–strain relations

Stress	Resulting strain in each direction		
	x	y	z
σ_x	$\dfrac{\sigma_x}{E}$	$-\dfrac{\nu\sigma_x}{E}$	$-\dfrac{\nu\sigma_x}{E}$
σ_y	$-\dfrac{\nu\sigma_y}{E}$	$\dfrac{\sigma_y}{E}$	$-\dfrac{\nu\sigma_y}{E}$
σ_z	$-\dfrac{\nu\sigma_z}{E}$	$-\dfrac{\nu\sigma_z}{E}$	$\dfrac{\sigma_z}{E}$

2.2 Rubber Elasticity

Hooke's law describes the linear stress–strain relation limited to small deformation. However, many polymers experience large deformation, which gives rise to nonlinear stress–strain responses. One example is elastomers. Elastomers are typified by natural rubber but also include a variety of synthetic polymers with similar mechanical behavior. In fact, most noncrystalizable polymers with reasonably high molecular weight are capable of being obtained in the rubber-like state. At low temperatures, the polymer is glassy with a high modulus ($\sim 10^9$ Pa). The modulus then falls through the glass transition region where the polymer is viscoelastic and the modulus becomes very rate- and temperature-dependent. At

a sufficiently high temperature the polymer becomes rubbery. However, all rubbery polymers do not show useful elastomer properties because they will flow irreversibly on loading unless they are cross-linked. The modulus of a linear polymer drops effectively to zero at a sufficiently high temperature when it behaves like a liquid. For cross-linked polymer the modulus will reach a plateau at about 10^6 Pa as the temperature increases.

Cross-linked rubbers possess the remarkable ability of being able to stretch to up to ten times their initial length and then retract rapidly to near their original dimensions when the force is removed. The molecular mechanism responsible for rubber elasticity is based on changes in chain conformation brought about by the overall strain (Figure 4). Clearly, the number of possible chain conformations must be fewer in case (c) than in case (a), resulting in a reduction of entropy.[2] The decreased conformational entropy results in a positive free energy for the stretched state, providing a driving force that causes the material to snap back when the stretching force is released. In this respect, elastomers differ fundamentally from metal springs. The latter develop retractive forces primarily because of increased interatomic distances, which correspond primarily to a change in enthalpy rather than entropy. Thus, in terms of free energy, the entropy term ΔS is primarily responsible for the free energy change ΔF in elastomers, according to Equation (12):

$$\Delta F = \Delta H - T\Delta S \tag{12}$$

Figure 4 Illustration of entropy reduction on application of force F to network chain: (a) chain at equilibrium; (b) chain as force is being applied; (c) final state with force applied.

whereas the enthalpy term ΔH is of prime importance in metal springs. The fundamental difference between elastomers and metal springs results in a quite different dependence of mechanical behavior on temperature. For elastomers, Equation (13) gives the temperature dependence of the shear modulus as

$$G = nRT = \frac{\rho RT}{M_c} \tag{13}$$

where n represents the number of network chains per unit volume, ρ is the density and M_c is the number-averaged molar mass of the chain length between cross-links. Equation (13) is analogous to the equation of state for ideal gases, $PV = nRT$, which is also based solely on entropy consideration. Neither theory provides any details of chemical structure, but rather involves the modes of molecular motion.

As shown in Equation (13), the shear modulus G increases as the length of chain between the cross-links is reduced. This means that the material becomes stiffer as the cross-link density increases and the network becomes tighter. Equation (13) also shows a surprising phenomenon that has been substantiated experimentally. The modulus of an elastomer increases with temperature, which is in contrast with almost every other material. The modulus increases with temperature because of the increased thermal or Brownian motion, which causes the stretched molecular segments to tug at their ''anchor points'' and try to assume a more probable coiled-up shape. This is a direct consequence of the deformation of elastomers being dominated by changes in entropy rather than internal energy.

The theory of rubber elasticity leads to a nonlinear stress–strain expression (Equation 14) for unidirectional stretching:

$$\sigma = C_0 \left(\lambda - \frac{1}{\lambda^2} \right. \tag{14}$$

where σ is the stress, $\lambda = L/L_0$ is the ratio of the final to the original length, called the stretch ratio, and C_0 is a constant. The stretch ratio λ is a different strain measurement of materials, and is related to the strain defined in Equation (2), i.e. $\lambda = 1 + \varepsilon$.

Equation (14) is valid for small extensions only as shown by Flory[2] and Treloar[3] through experiments. However, it suffers from the same defects as afflict the ideal gas equation, which makes no allowance for such factors as molecular attractive forces or spatial considerations. An important semi-empirical improvement is given by Equation (15), the Mooney–Rivlin equation:[4–6]

$$\sigma = C_1 \left(\lambda - \frac{1}{\lambda^2} \right. + C_2 \left(1 - \frac{1}{\lambda^3} \right. \tag{15}$$

Table 3 Mooney–Rivlin constants

Elastomer	Natural rubber	Butyl rubber	Styrene–butadiene rubber	Ethene–propene rubbers	Polyacrylate rubbers	Silicon rubbers	Polyurethanes
C_1	2.0	2.6	1.8	2.6	1.2	0.75	3
(10^5 N m^{-2})	(0.9–3.8)	(2.1–3.2)	(0.8–2.8)	(2.1–3.1)	(0.6–1.6)	(0.3–1.2)	(2.4–3.4)
C_2	1.5	1.5	1.1	2.5	2.8	0.75	2
(10^5 N m^{-2})	(0.9–2)	(1.4–1.6)	(1.0–1.2)	(2.2–2.9)	(0.9–4.8)	(0.3–1.1)	(1.8–2.2)

where C_1 and C_2 are empirical constants whose values are given in Table 3 for several elastomers.[7]

In the early 1970s Ogden[8] extended Mooney–Rivlin's model and proposed a more general form for the strain energy (Equation 16) through which the stress–strain relation can be derived:

$$W = \sum_{i=1}^{I} \frac{2\mu_i}{\alpha_i}(\lambda_1^{\alpha_i} + \lambda_2^{\alpha_i} + \lambda_3^{\alpha_i}) \qquad (16)$$

where λ_1, λ_2 and λ_3 are three principal stretch ratios representing general three-dimensional deformation, and I is the number of terms used in the series defined by constants μ_i and α_i to fit experimental data. A nonlinear stress–strain relation is obtained by equating the stresses to the derivatives of the strain energy in Equation (16) with respect to the stretch ratios. Ogden,[8] as well as Treloar,[9] Twizell and Ogden,[10] have demonstrated that Equation (16) is capable of representing elastomers under large, general three-dimensional deformation. The Ogden equation (Equation 16) has also been modified[11,12] to model compressible rubber (such as foam).

3 TIME- AND TEMPERATURE-DEPENDENT BEHAVIOR OF POLYMERS

3.1 Viscoelastic Model

A distinctive feature of the mechanical behavior of polymers is that the way in which they respond to an applied stress depends very much on the rate and duration of loading. This is in direct contrast to the behavior of elastic solids such as metals and ceramic, for which, at least at low temperatures and small deformation, the stress is proportional to the strain and independent of loading rate. The behavior of most polymers can be considered as being somewhere between that of elastic solids and liquids. At low temperature and high strain rate they display elastic behavior, whereas at high temperature and low strain rate they behave in a viscous manner. Polymers are therefore termed viscoelastic because they exhibit aspects of both viscous and elastic types of behavior. Because of their chain-like structure, polymers are not perfectly elastic bodies and deformation is accompanied by a complex series of long- and short-range cooperative molecular rearrangements. Consequently, the mechanical behavior is dominated by viscoelastic phenomena, in contrast to materials such as metal and glass where atomic adjustments under stress are more localized and limited. Some polymers show viscoelastic behavior in a striking way. For example, silicon putty flows when it is left alone but bounces like a rubber ball when loaded quickly.

The early work on viscoelasticity was performed on silk, rubber, and glass, and it was concluded that these materials exhibited a ''delayed elasticity''. This delayed elasticity is manifested in the observation that the imposition of a stress resulted in an instantaneous strain that continued to increase more slowly with time. It is this delay between cause and effect that is fundamental to the observed viscoelastic response. The three major examples of this hysteresis effect are: creep, where there is a delayed strain response after the rapid application of a stress; stress relaxation, in which the material is quickly subjected to a strain and a subsequent delay of stress is observed; and dynamic response of polymer to the imposition of a steady sinusoidal stress, which produces a strain oscillating with the same frequencies but out of phase with the stress.

To be of any practical use, an object made from a polymer material must be able to retain its shape when subjected to a small force over a long period of time. This dimensional stability is an important consideration in choosing a polymer for a polymer product. No one wants a plastic telephone receiver that sags after sitting in its cradle for several weeks. Creep can be considered as a progressive increase in strain, observed over an extended time period, in a polymer subjected to a constant stress. Stress relaxation involves the decay of stress required to maintain a constant deformation.

Mechanical models are often used to discuss the viscoelastic behavior of polymers. In Figure 5 are shown three mechanical models of linear viscoelastic behavior, namely: the Maxwell model, the Voigt model, and the ''standard linear'' model, all of which are composed of combinations of linear springs with spring constant E and dashpots with coefficient of viscosity η. A linear spring

Figure 5 Models of linear viscoelasticity: (a) Maxwell; (b) Voigt; (c) standard linear solid.

produces instantaneous deformation proportional to the load. A dashpot produces a velocity proportional to the load at any instant. Under creep conditions, a constant load is applied to the polymer, and the strain response of the material for the Maxwell model is given according to Equation (17):

$$\varepsilon(t) = \left(\frac{1}{E} + \frac{1}{\eta}t \quad \sigma \right. \tag{17}$$

The creep function (compliance function) is defined as the strain under a unit stress, i.e. $\sigma = 1$. For instance, the creep function for the Maxwell model is given by Equation (18):

$$c(t) = \frac{\varepsilon(t)}{\sigma} = \left(\frac{1}{E} + \frac{1}{\eta}t \right. \tag{18}$$

The strain response and creep functions for the Voigt model and the standard linear model are given by Equations (19) and (20), respectively:

$$\varepsilon(t) = \frac{1}{E}(1 - \mathrm{e}^{-(E/\eta)t})\sigma$$

$$c(t) = \frac{\varepsilon(t)}{\sigma} = \frac{1}{E}(1 - \mathrm{e}^{-(E/\eta)t}) \tag{19}$$

$$\varepsilon(t) = \frac{1}{E_\mathrm{R}} \quad 1 - \left(1 - \frac{\tau_\varepsilon}{\tau_\sigma} \quad \mathrm{e}^{-t/\tau_\sigma} \quad \sigma \right.$$

$$c(t) = \frac{\varepsilon(t)}{\sigma} = \frac{1}{E_\mathrm{R}} \quad 1 - \left(1 - \frac{\tau_\varepsilon}{\tau_\sigma} \quad \mathrm{e}^{-t/\tau_\sigma} \right. \tag{20}$$

where $\tau_\varepsilon = \eta_\mathrm{m}/E_\mathrm{m}$ and $\tau_\sigma = \eta_\mathrm{m}(1/E_\mathrm{m} + 1/E_\mathrm{R})$.

Interchanging the roles of stress and strain, we obtain the relaxation function, which is the response stress corresponding to constant strain. The relaxation function $k(t)$ is the stress that must be applied in order to produce a strain that changes at $t = 0$ from zero to unity and remains at unity thereafter. Equations (21–23) give the respective relaxation functions for the Maxwell, Voigt, and standard linear models:

$$\sigma(t) = E\mathrm{e}^{-(E/\eta)t}\varepsilon \quad k(t) = \frac{\sigma(t)}{\varepsilon} = E\mathrm{e}^{-(E/\eta)t} \tag{21}$$

$$\sigma(t) = [\eta\delta(t) + E]\varepsilon \quad k(t) = \frac{\sigma(t)}{\varepsilon} = [\eta\delta(t) + E] \tag{22}$$

$$\sigma(t) = E_\mathrm{R} \quad 1 - \left(1 - \frac{\tau_\sigma}{\tau_\varepsilon} \quad \mathrm{e}^{-t/\tau_\varepsilon} \quad \varepsilon \right.$$

$$k(t) = \frac{\sigma(t)}{\varepsilon} = E_\mathrm{R} \quad 1 - \left(1 - \frac{\tau_\sigma}{\tau_\varepsilon} \quad \mathrm{e}^{-t/\tau_\varepsilon} \right. \tag{23}$$

Here, we have used the symbol $\delta(t)$ to indicate the unit-impulse function that is infinity at $t = 0$ and zero elsewhere.

The creep and relaxation function for these three models are shown in Figures 6 and 7. For the Maxwell solid, a sudden application of a load induces an immediate deflection by the elastic spring, which is followed by "creep" of the dashpot. On the other hand, a sudden

Figure 6 Creep functions of: (a) Maxwell; (b) Voigt; (c) standard linear solid.

Figure 7 Relaxation functions of: (a) Maxwell; (b) Voigt; (c) standard linear solid.

deformation produces an immediate reaction by the spring, which is followed by stress relaxation according to an exponential law (Equation 21). The factor η/E, with the dimensions of time, may be called the relaxation time. It characterizes the rate of decay of the force.

For a Voigt solid, the sudden application of force will produce no immediate deflection because the dashpot, arranged in parallel with the spring, will not move instantaneously. Instead, as shown by Equation (19) and Figure 6(b), a deformation will be built up gradually while the spring takes a greater and greater share of the load. The dashpot displacement relaxes exponentially. Here, the ratio η/E is again a relaxation time. It characterizes the rate of relaxation of the deflection.

For the standard linear solid, a similar interpretation is applicable. The constant τ_ε is the time of relaxation of load under the condition of constant deflection (see Equation 23), whereas the constant τ_σ is the time of relaxation of deflection under the condition of constant load (see Equation 20). As t approaches infinity, the dashpot is completely relaxed, and the stress–strain relation becomes that of the springs, as is characterized by the constant E_R, in Equations (20) and (23). Therefore, E_R is called the relaxed elastic modulus.

Maxwell introduced the model represented by Equation (17) with the idea that all fluids are elastic to some extent. Lord Kelvin showed the inadequacy of the Maxwell and Voigt models in accounting for the rate of dissipation of energy in various materials subjected to cyclic loading. Kelvin's model is commonly called the standard linear model because it is the most general relationship to include the load, the deflection, and their first (commonly called "linear") derivatives. More general models may be built by adding more and more elements to the Kelvin model. Equivalently, we may add more and more exponential terms to the creep function or to the relaxation function.

The most general formulation under the assumption of linearity between cause and effect is due to Boltzmann. In the one-dimensional case, we may consider a simple bar subjected to a stress $\sigma(t)$ and strain $\varepsilon(t)$. The strain $\varepsilon(t)$ is caused by the total history of the loading up to time t. If the function $\sigma(t)$ is continuous and differentiable, then in a small time interval $d\tau$ at time τ the increment of loading is $(d\sigma/d\tau)\,d\tau$. This increment remains acting on the bar and contributes an element $d\varepsilon(t)$ to the strain at time t, with a proportionality constant c depending on the time interval $t-\tau$. Hence, we may write Equation (24):

$$d\varepsilon(t) = c(t-\tau)\frac{d\sigma(\tau)}{d\tau}\,d\tau \tag{24}$$

Let the origin of time be taken at the beginning of motion and loading. Then, on summing over the entire history, which is permitted under the Boltzmann hypothesis, we obtain Equation (25):

$$\varepsilon(t) = \int_0^t c(t-\tau)\frac{d\sigma(\tau)}{d\tau}\,d\tau \tag{25}$$

A similar argument, with the role of σ and ε interchanged, gives Equation (26):

$$\sigma(t) = \int_0^t k(t-\tau)\frac{d\varepsilon(\tau)}{d\tau}\,d\tau \tag{26}$$

The functions $c(t-\tau)$ and $k(t-\tau)$ are the creep function (compliance function) and relaxation function defined earlier, and are zero when $t-\tau$ is less than zero.

The Maxwell, Voigt, and standard linear solid models are special examples of Boltzmann formulation. More generally, we can write the relaxation function in the form of Equation (27):

$$k(t) = \sum_{n=0}^{N} \alpha_n e^{-\upsilon_n t} \tag{27}$$

which is a generalization of Equation (23). If we plot the amplitude α_n associated with each characteristic frequency υ_n on a frequency axis, we obtain a series of

lines that resemble an optical spectrum. Hence, $\alpha_n(\upsilon_n)$ is called a spectrum of realization function. A generalization to a continuous spectrum may be desired. In some cases, experimental results on relaxation, creep, and hysteresis cannot be reconciled unless a continuous spectrum is utilized.

3.2 Dynamic Mechanical Thermal Analysis

Many experimental techniques are used to measure viscoelastic properties. Measurement of the response in deformation of a material to periodic stress, e.g. during forced vibration, shows that stress and strain are not in phase, i.e. the strain lags behinds the stress by a phase angle δ. Thus, the variation of stress and strain with time can be given by expressions of the type shown in Equation (28):

$$\varepsilon = \varepsilon_0 \sin wt \quad \sigma = \sigma_0 \sin(wt + \delta) \tag{28}$$

which can be rewritten to give Equation (29):

$$\begin{aligned} \sigma &= \sigma_0 \sin wt \cos\delta + \sigma_0 \cos wt \sin\delta \\ &= \varepsilon_0 E_1 \sin wt + \varepsilon_0 E_2 \cos wt \end{aligned} \tag{29}$$

where the dynamic moduli $E_1 = (\sigma_0/\varepsilon_0)\cos\delta$ and $E_2 = (\sigma_0/\varepsilon_0)\sin\delta$ are in phase and 90° out of phase with the strain, respectively; E_1 and E_2 are also called storage and loss moduli. The phase angle δ is obtained according to Equation (30):

$$\tan\delta = \frac{E_1}{E_2} \tag{30}$$

It is more convenient to use complex notation. For such a purpose, let $\varepsilon^* = \varepsilon_0 e^{iwt}$ and $\sigma^* = \sigma_0 e^{i(wt+\delta)}$, then Equation (31) is formed:

$$E^* = \frac{\sigma^*}{\varepsilon^*} = \frac{\sigma_0}{\varepsilon_0} e^{i\delta} = \frac{\sigma_0}{\varepsilon_0}\cos\delta + i\frac{\sigma_0}{\varepsilon_0}\sin\delta = E_1 + iE_2 \tag{31}$$

The shear modulus may be written as a complex modulus in the same way, giving Equation (32):

$$G^* = G_1 + iG_2 \tag{32}$$

where the real and imaginary parts G_1 and G_2 are the storage and loss shear moduli, respectively. The imaginary parts of the complex moduli are damping terms determining the dissipation of energy as heat when the material is deformed; this is why they are called loss moduli. The real parts of the complex moduli are terms determining the amounts of recoverable energy stored as elastic energy; hence, they are called storage moduli.

There are five main experimental approaches for measuring the dynamic mechanical properties of a sample: transient measurements (creep and stress relaxation); low-frequency vibrations (free oscillation methods); high-frequency vibrations (resonance methods); forced vibrations (nonresonance methods); and wave propagation methods. For a full understanding of the viscoelastic behavior of polymers, data are required over a wide range of frequency (or time) and temperature. The number of experiments required can be reduced sometimes by using the equivalency of creep and stress relaxation, the dynamic mechanical data, or the equivalency of time and temperature. Nevertheless, the advantages and limitations of various methods need to be recognized. The approximate frequency scale for each of the five techniques mentioned above is indicated in Figure 8.[13] The first four approaches are reviewed below. The reader is referred to the literature for various wave propagation methods to measure dynamic mechanical properties at kilohertz and megahertz frequency ranges.[14,15]

3.2.1 Transient Measurements: Creep and Stress Relaxation

Because of the simplicity of a creep experiment, a wide variety of experimental techniques have been used in different laboratories, and many have never been described in a publication. The constant force is often applied by a dead weight, and the displacement is measured by a differential transformer, traveling microscope, or deflection of a light beam. The measured displacement gives the strain variation with time and the creep function, $c(t)$, such as that in Equations (18–20) and (25), is obtained.

Any of the experimental techniques for creep experiments can, in principle, be used for studying stress relaxation if the force (stress) can be measured as a function of time while the deformation is held constant. There are, in general, three ways of keeping constant

Figure 8 Approximate frequency scales for different experimental techniques.

strain: by continuous adjustment of the force as the stress in the sample relaxes, which can be done by an automatic servomechanism;[16] by applying more than enough force, with a stop to limit the deformation;[17] and by straining a stiff spring element in series with the sample. The apparatus used for stress relaxation measurements varies in complexity with the physical nature of the sample: simplest for an elastomer and becoming more sophisticated when the polymer is more rigid. One type of experimental set-up[18] is shown in Figure 9, where a force transducer records the stress with an automatic adjustment to zero displacement. Experimental methods and procedures for stress relaxation have been reviewed in detail by Bergen.[19]

3.2.2 Torsional Pendulum: Free Vibration

A study of the mechanical damping and shear modulus under free vibration can be made using a torsional pendulum (Figure 10).[20] The specimen is firmly fixed at one end and the other end is clamped to a disc, with a large moment of inertia, which can move freely. Because the polymer sample should not be under a tensile stress, the suspension wire supporting the disc is passed over a pulley and the weight of the disc and sample are counterbalanced by loading the end. If the disc is subjected to an angular displacement and then released, the sample will twist backwards and forwards about the vertical axis. The oscillations stimulated in the sample are picked up by an arm attached to the rigidly fixed end held in torsion bars, and transmitted to a recorder by a linear variable differential transformer. The sample movements are traced as a series of oscillations whose frequency is a function of the physical state of the sample.

A quantitative measure of the damping is provided by the logarithmic decrement Δ, defined as the logarithmic decrease in amplitude per cycle. It is calculated from the ratio of amplitudes of any two successive oscillations using Equation (33):

$$\Delta = \ln\left(\frac{A_1}{A_2}\right) = \ln\left(\frac{A_2}{A_3}\right) = \cdots = \ln\left(\frac{A_n}{A_{n+1}}\right) \qquad (33)$$

For a specimen with circular cross-section of radius a and length L, the phase angle, storage modulus and loss shear modulus can also be derived from the data[21] according

Figure 10 Schematic diagram of a torsion pendulum and the damping of the oscillations for a viscoelastic material. (Reproduced by permission of Stanley Thornes Publishers from J.M.G. Cowie, *Polymers: Chemistry and Physics of Modern Materials*, Blackie Academic & Professional, London, 1977.)

to Equation (34):

$$\tan\delta = \frac{\Delta/\pi}{1-\Delta^2/4\pi^2} \quad G_1 = \frac{2LIw^2}{\pi a^4}\left(1-\frac{\Delta^2}{4\pi^2}\right.$$

$$G_2 = \frac{2LIw^2}{\pi a^4}\frac{\Delta}{\pi} \tag{34}$$

where I is the polar moment of inertia of the disc. Usually Δ is much less than unity so that Equation (34) can be simplified to give Equation (35):

$$\tan\delta = \frac{\Delta}{\pi} \qquad G_1 \approx \frac{2LIw^2}{\pi a^4} = G \tag{35}$$

When the cross-section of the sample is not circular, a geometric correction factor needs to be introduced in the above expressions for G_1, G_2, and δ. The values of the geometric factor for various geometries are given by Rodriguez.[22]

A torsion pendulum is a particularly useful device for examining the modulus and internal friction of polymers. When the sample geometry is in the form of a cone-and-plate or concentric cylinders, the pendulum can be used for very weak gels, which are hard to characterize in conventional testing apparatus. The method can cover the complete range of moduli encountered in polymeric systems but is confined to a relatively narrow frequency range of 0.01–10 Hz.

3.2.3 Vibration Reed: Resonance

This formerly popular industrial method employs a small sample in the form of a thin strip that is clamped firmly at one end, leaving the other end free. The clamped end of the system is then vibrated laterally at a given frequency and the amplitude of the vibration induced at the free end of the sample is recorded. A range of frequencies (200–1500 Hz[23,24]), wide enough to ensure that it encompasses the resonant frequency of the sample f_r, is then examined. The resonant frequency is detected as the maximum of a graph of amplitude against frequency.

A complete treatment of the viscoelastic behavior of the vibrating reed has been given by Bland and Lee.[25] If mechanical loss is small, the modulus E can be obtained from the elasticity solution, and $\tan\delta$ from the resonance curve. For a cantilever of density ρ, length L and thickness h, the resonant frequency of the fundamental mode is given by Equation (36):

$$f_r = \frac{1}{2\pi}\frac{1.875^2}{L^2}\quad\frac{\overline{E}}{\rho}\frac{h}{2\sqrt{3}} \tag{36}$$

from which E is obtained, as shown in Equation (37):

$$E = 38.24\frac{L^4\rho}{h^2}f_r^2 \tag{37}$$

The sensitivity to sample dimensions can give rise to large uncertainty in interspecimen comparisons. This sensitivity is similar to that observed with free torsional vibration.

An analogy between the viscoelastic reed and an equivalent electrical circuit[26] gives Equation (38):

$$\tan\delta = \frac{\Delta f}{f_r} \tag{38}$$

where Δf, the bandwidth, is the difference between the frequencies at which the amplitude of vibration is $1/\sqrt{2}$ of the maximum value (see Figure 11). This technique is not as useful as the torsional pendulum but covers the higher frequency range of 10–1000 Hz.

3.2.4 Forced Vibration: Nonresonance

Several types of instrument can be used for this type of test, and these are usually limited to measurements on rigid polymers or rubbers. One such instrument is shown in Figure 12. The sample (C) is attached firmly at each end to a strain gauge; one of these is a force transducer measuring the applied sinusoidal force and the other records the sample deformation. A sinusoidal tensile stress of a given frequency can be generated in the vibrator (A). Typically, strains are measured by an unbonded strain-gauge transducer. The signals are then fed to a phase meter, which provides a direct reading of the relative amplitudes and the phase difference. This

Figure 11 Resonance curve for the vibrating reed.

Figure 12 Schematic diagram of apparatus for measuring the dynamic mechanical response using a nonresonance technique.

provides values of the tensile storage and loss moduli as well as the phase angle.

A second version now widely used for these measurements is the Polymer Laboratories DMTA instrument. Several damping arrangements are available for the sample so that measurements may be made in the bending, shear, or tensile modes. In the bending mode the sample, in the form of a small bar, is clamped firmly at both ends and the central point is vibrated by means of a ceramic drive shaft. This can be driven at frequencies selected from the range 0.01–200 Hz. The applied stress is proportional to the AC current fed to the drive shaft and the strain is detected using a transducer that measures the displacement of the drive clamp. Temperature can be controlled over the range 120–770 K, and experiments can be done either isothermally or nonisothermally by ramping the temperatures up and down at various fixed rates.

3.3 Effects of Temperature on Mechanical Properties

In considering the effects of temperature on the mechanical properties of polymers, we will follow closely the discussion by Aklonis and MacKnight.[27] A polymer sample of unit cross-sectional area is subjected to an instantaneous tensile strain that is thereafter maintained constant. The stress is monitored as a function of time, and the tensile stress relaxation modulus is obtained. Let t be any arbitrary time, perhaps 10 s. Next, the stress is removed, allowing the sample to relax, and the temperature is changed. The same experiment is carried out yielding the Young's modulus, E (10 s), at this new temperature. The experiment is repeated at many temperatures to yield the ''ten-second tensile relaxation modulus'' as a function of temperature.

Figure 13 Schematic modulus–temperature curve showing various regions of viscoelastic behavior. (Reproduced by permission of John Wiley & Sons from J.J. Aklonis, W.J. MacKnight, *Introduction to Polymer Viscoelasticity*, 2nd edition, Wiley, New York, 1983.)

The types of behavior most often observed are shown in Figure 13, which shows idealized modulus–temperature curves for typical linear and cross-linked amorphous polymers. In this plot, four regions of viscoelastic behavior are defined. At low temperatures, where the modulus is higher than 10^9 Pa, the polymer is hard and brittle. This is the glassy region. The glassy modulus, E_1, is a slowly decreasing function of temperature and is a useful parameter for characterizing polymeric behavior. In this glassy region, thermal energy is insufficient to surmount the potential barriers for rotational and translational motions of segments of the polymer molecules. The chain segments are essentially ''frozen'' in fixed positions on the sites of a disordered quasi-lattice with their segments vibrating around these fixed positions much like low-molecular-weight molecules in a molecular crystal. With increasing temperature, the amplitude of vibrational motion becomes greater and eventually the thermal energy becomes roughly comparable to the potential energy barriers to segment rotation and translation. In this temperature region, the polymer is at the glass transition temperature, where short-range diffusional motions begin. Segments are free to ''jump'' from one lattice site to another and the brittle glass becomes a resilient leather.

This phenomenon is accompanied by a modulus decrease of several orders of magnitude, as indicated in Figure 13. The breadth of this transition region ranges from 5 °C to more than 20 °C, depending on the nature of the polymer in question. The transition region may be characterized by two parameters. The temperature at which the 10-s modulus reaches 10^8 Pa is termed the inflection temperature, T_i, and the negative slope of the curve ($\tan\theta$) at this point is termed s. Values of these characteristic viscoelastic parameters for several amorphous polymers are listed in Table 4.[27]

As the temperature is increased further, the modulus again reaches a plateau region. This rubbery plateau is characterized by the modulus E_2, as shown in Figure 13. In this temperature interval, the short-range diffusional motions of the polymer segments that initially gave rise to the glass transition occur much faster than the measurement time of 10 s. On the other hand, the long-range cooperative motion of chains that would result in translational motions of complete molecules is still greatly restricted by the presence of strong local interactions between neighboring chains. In the case of the cross-linked material, these interactions consist of primary chemical bonds. In the linear polymer, they are known as entanglements, and their precise nature is not clear. In any case, in the rubbery plateau region, segments

of chains reorient relative to each other but large-scale translational motion does not occur.

The viscoelastic responses of linear and cross-linked polymers through the rubbery plateau region are essentially identical. As the temperature is increased further, however, differences between these two categories of polymers become evident (Figure 13). First consider a cross-linked network. As temperature is increased, the cross-links consisting of primary chemical bonds remain intact, preventing the chains from translating relative to one another. Although the modulus changes slightly with temperature in the rubbery plateau region of a cross-linked polymer, this change is small compared to changes exhibited during the glass transition. Thus, to a first approximation, the modulus will remain constant for a cross-linked rubber up to temperatures where chemical degradation begins to occur. The situation is quite different for a linear polymer. In this case, increasing temperature causes molecular motions to become more and more large scale until eventually whole polymer molecules begin to translate. When the temperature is high enough, local chain interactions are no longer of sufficiently high energy to prevent molecular flow. This area of the 10-s modulus temperature curve is called the flow region.

3.4 Time–Temperature Superposition

It is thought that there is a general equivalency between time (frequency) and temperature. For instance, a polymer that displays rubbery characteristics under a given set of testing conditions can show glass behavior by either reducing the temperature or increasing the testing rate or frequency. Leaderman[28] was the first to suggest that in viscoelastic materials time and temperature are equivalent, meaning that data at one temperature can be superimposed upon data taken at a different temperature merely by shifting curves. Williams et al.,[29] Tobolsky,[30] and Ferry[18] have worked out this suggestion and demonstrated the validity of the principle. With their procedures it is possible to convert short-term stress–relaxation data at widely different temperatures to a single curve covering many decades of time at some reference temperature. This is accomplished by translating the small curves collected at different temperatures along the $\log t$ axis until

they are all superimposed to form a large composite curve spanning a long period of time.

Figure 14[31,32] is chosen as an example showing the curves of polyisobutylene. These curves are first corrected (reduced) for density and temperature. An arbitrary temperature T_s is selected as the reference temperature. The reduced modulus values are calculated using Equation (39):

$$E(t)_{\text{reduced}} = \frac{T_s}{T}\frac{\rho_s}{\rho}E(t) \tag{39}$$

where $E(t) = \sigma(t)/\varepsilon$ is the modulus in a stress relaxation test. The correction comes from the kinetic theory of rubber elasticity; it is relatively small and is sometimes neglected. After this reduction the experimental curves are replotted, as shown on the left side of Figure 14. These reduced curves can now be shifted, one at a time, with respect to the reference curve (at $T_s = 25\,^{\circ}\text{C}$), until portions of the curves superimpose to give a master curve, as shown on the right side of Figure 14. The amount by which each reduced modulus has to be shifted along the logarithmic time axis in making the master curve – the so-called shift factor – is a function of temperature (see upper right corner of Figure 14). The curve obtained at each temperature is shifted by an amount as shown in Equation (40):

$$(\log t - \log t_s) = \log\left(\frac{t}{t_s}\right) = \log a_T \tag{40}$$

The parameter a_T is called the shift factor and is positive if the movement of the curve is to the left of the reference and negative for a move to the right. The shift factor is a function of temperature only and decreases with increasing temperature. It is, of course, unity at the reference temperature, T_s. The superposition principle also applies to creep data.

Williams et al.[29] proposed that a_T could be given by an equation of the form shown in Equation (41):

$$\log a_T = \frac{-C_1(T - T_s)}{C_2 + (T - T_s)} \tag{41}$$

where C_1 and C_2 are constants and T_s is the reference temperature. This is normally called the WLF equation and was originally developed empirically. It holds extremely well for a wide range of polymers in the vicinity of the glass transition. If T_s is taken as T_g – the glass transition temperature measured by a static method such as dilatometry – then, according to Equation (42):

$$\log a_T = \frac{-C_1^g(T - T_g)}{C_2^g + (T - T_g)} \tag{42}$$

and the new constants C_1^g and C_2^g become "universal", with values of 17.4 and 51.6 K, respectively. In fact, the constants vary somewhat from polymer to polymer, but it is often quite safe to assume the universal values because they usually give shift factors that are close to measured values.

Figure 14 Time–temperature superposition principle illustrated with polyisobutylene data. The reference temperature of the material curve is 25 °C. The inset graph gives the amount of curve shifting required at the different temperature. (Reproduced by permission of Academic Press from E. Catsiff, A.V. Tobolsky, *J. Colloid Sci.*, **10**, 375 (1955).)

The WLF master curve produced by superposing data obtained at different temperatures is a very useful way of presenting the mechanical behavior of a polymer. The WLF equation is also useful in predicting the mechanical behavior of a polymer outside the range of temperature and frequency (or time) for which experimental data are available. Although the WLF equation was developed originally by curve fitting, it is possible to justify it theoretically from considerations of free volume.[29]

4 ULTIMATE PROPERTIES OF POLYMERS AND RUBBERS

4.1 General Stress–Strain Diagram

The strength properties of solids are illustrated most simply by a stress–strain diagram, which describes the behavior of a homogeneous specimen of uniform cross-section subjected to uniaxial tension. Three important types of stress–strain curves are illustrated in Figure 15. The brittle, plastic stress–strain curve is linear up to fracture at about 1–2% elongation. Typical stresses at break are of the order of 6×10^7 Pa. Ordinary polystyrene behaves in this way. An example of a tough plastic is polyethylene, which is semicrystalline, with the amorphous portions above T_g. Its Young's modulus, given by the initial slope of the stress–strain curve, is somewhat lower than that of the brittle, glassy plastic (see Figure 15). Typically, this class of polymer exhibits a yield point, followed by extensive elongation at almost constant stress. This is called the plastic flow region. Stresses in the range of 2–5 $(\times 10^7)$ Pa are commonly exhibited in this range. Extension at constant stress in the plastic flow region is often referred to as cold drawing.

Figure 15 Stress–strain behavior of three types of polymers. (Reproduced by permission of John Wiley & Sons from E. Catsiff, A.V. Tobolsky, *J. Polym. Sci.*, **19**, 111 (1956).)

Finally, the polymer strain hardens and then ruptures. The third type of stress–strain curve is that exhibited by elastomers. The equation of state for rubber elasticity governs here, with its peculiar nonlinear curve.

Elongation to break for both the tough plastic and the elastomer may be of the order of several hundred percent and is indicated by the dot at the end of the curve. For crystallizing elastomers such as natural rubber, the curve swings upward sharply at the point of crystallization, and tensile strengths of 14–34 MPa are common. Noncrystallizing elastomers have much lower tensile strengths, often below 7 MPa. With the addition of reinforcing fillers, such as finely divided carbon black, the tensile strength is much increased. Of course, this latter material is widely used for automobile tires, one of the toughest materials known. The moduli and strengths of some typical polymers are listed in Table 5.[33]

There are several terms in use that describe the "strength" of a polymer. The tensile strength describes the stress to break the material in a simple tension test. The tensile strength is certainly important, but in engineering practice a polymer is rarely stressed so greatly that it breaks immediately. Toughness of the polymer is frequently a more useful parameter. The toughness is measured by the area under the stress–strain curve. This area has the units of energy per unit volume and is the work expended in deforming the material. The deformation may be elastic and recoverable, or permanent (irreversible deformation). Elastic energy is stored in the sample in terms of energy per unit volume.

4.2 Cold Drawing in Crystalline Polymers

The tough plastic in Figure 15 is shown to have a yield point, followed by a region of cold drawing at almost constant stress. There are two basic causes for this phenomenon. First, for rubber-toughened amorphous plastics, the region of cold drawing is where extensive orientation of the chains takes place, accompanied by significant viscoelastic flow. Second, for semicrystalline polymers with amorphous portions above T_g, cold drawing rearrangement of the chains takes place in a characteristic complex manner that begins with necking. A neck is a narrowing down of a portion of the stressed material to a smaller cross-section. This is a form of shear yielding. The neck grows at the expense of the material at either end, eventually consuming the entire specimen.

In the region of the neck, a very extensive reorganization of the polymer is taking place. Spherulites are broken up, and the polymer becomes oriented in the direction of stretch. The number of chain folds decreases, and the number of tie molecules between the new fibrils is increased. The crystallization is usually enhanced by

Figure 16 Proposed mechanism of reorientation of crystalline structures during necking. (Reproduced by permission of John Wiley & Sons from A. Peterlin, *J. Polym. Sci.*, **9C**, 61 (1965).)

the chain alignment. At the end of the reorganization, a much longer, thinner, and stronger fiber or film is formed.

This phenomenon is easily demonstrated at home or in the classroom. A strip of polyethylene film, perhaps with print on it, is satisfactory. The strip is slowly stretched between the hands at room temperature, and the neck will form after several percent elongation. Such a material can then be elongated by 2–5 times its original length. Draw ratios can be significantly higher under more scientific conditions.

The molecular reorganization illustrated in Figure 16[34] has attracted the attention of the theoreticians.[35,36] Does the polymer actually melt under stress, and then reorganize, or do the crystals themselves rotate? At this point the evidence seems to be divided between the two possibilities.

It must be pointed out that drawing operations are critically important in the manufacture of fibers such as nylon and rayon. In the case of nylon, the polymer is spun in the melt state. The fiber is then cooled until it crystallizes, and finally stretched with a draw ratio of 4 : 8.

The case of rayon is slightly complicated because an alkaline solution of sodium cellulose xanthate is spun. The nascent fiber is spun into an acid bath, which removes the xanthate groups, thus precipitating the polymer. As it precipitates, it crystallizes. The fiber is then stretched

Table 5 Mechanical properties of polymers (unmodified) (moduli in 10^9 Pa; strengths in 10^7 Pa)

wet, approximately 4–7 times its original length. In both cases, the fibers are highly oriented, as shown by X-ray studies. The high degree of orientation contributes to the high strength of such fibers.

4.3 Temperature and Pressure Effects on Yield Stress

For polymers, rather unusual features are revealed when the yield stress of the same polymer is measured in simple uniaxial tension and compression. Conventional yielding criteria such as the Tresca and von Mises criteria[21] predict that the yield stress should be the same in both cases. This is what is found for metals, but for polymers the compressive yield stress is usually higher than the tensile yield stress. This difference between the compressive and tensile yield stress can be taken as an indication that the hydrostatic component of the applied stress is exerting an influence upon the yield process. This can be demonstrated more directly by measuring the tensile yield stress under the action of an overall hydrostatic pressure. The results of such measurements on different polymers are shown in Figure 17.[37] It can be seen that there is a clear increase in the yield stress with hydrostatic pressure. In general, it is found that the yield stresses of amorphous polymers show larger pressure dependence than those of crystalline polymers. There is no significant change in the yield stresses of metals at similar pressures, but it is quite reasonable to expect that the physical properties of polymers will change at these relatively low pressures. They tend to have much lower bulk moduli than metals and so undergo significant volume changes on pressurization.

Plastic deformation, like other aspects of the mechanical behavior of polymers, has a strong dependence upon the testing rate and temperature. Typical behavior is illustrated in Figure 18[21] for a glassy thermoplastic deformed in tension. At a given strain rate the yield stress drops as the temperature is increased, and the yield stress falls approximately linearly to zero at the glass transition temperature when the polymer glass becomes a rubber. If the strain rate is increased and the temperature held constant, the yield stress increases.

The behavior of semicrystalline polymers is rather similar, with the main difference being that the yield stress drops to zero at the melting temperature of the crystals rather than at the T_g (glass transition temperature). Between T_g and T_m (melting temperature), the noncrystalline areas are rubbery and the material gains its strength from the crystalline regions that reinforce the rubbery matrix. If the temperature of a semicrystalline polymer is reduced below T_g, it behaves more like a glassy polymer and the crystals do not have such a significant strengthening effect.

4.4 The Brittle–Ductile Transition

Many materials are ductile under certain testing conditions, but when these conditions are changed, e.g. by reducing the temperature, they become brittle. This type of behavior is also encountered in steels and is very common with polymers. In this section, we follow to a large extent the discussion given by Young and Lovell.[21] Figure 19(a)[21] shows how the strength of poly(methyl methacrylate) (PMMA) varies with testing temperature. At low temperatures the material fails in a brittle manner dictated by brittle break strength σ_b. When the testing temperature is raised to just above room temperature the polymer undergoes general yielding (indicated by yielding strength σ_Y) and brittle fracture is suppressed. This type

Figure 19 Ductile to brittle transition: (a) variation with temperature of the brittle strength measured in flexure (σ_b) and yield strength measured in tension (σ_y) for PMMA; (b) effect of strain rate on the transition. Curves for a higher strain rate are drawn as dashed lines. (Reproduced by permission of Stanley Thornes Publishers from R.J. Young, P.A. Lovell, *Introduction to Polymers*, 2nd edition, Chapman & Hall, London, 1995.)

of brittle–ductile transition has been explained in terms of brittle fracture and plastic deformation being independent processes that have a different dependence on temperature, as shown schematically in Figure 19(b).[21] The yield stress increases more rapidly as the temperature is reduced, and at a critical temperature it becomes higher than the stress required to cause brittle fracture. The temperature at which this occurs corresponds to that of the brittle–ductile transition, T_b, and it is envisaged that the process that occurs during deformation is that which can take place at the lowest stress, i.e. brittle fracture at $T < T_b$ and general yielding at $T > T_b$.[21]

There is an added complication for polymers, i.e. the strong dependence of the mechanical properties upon strain rate as well as upon temperature. For example, nylons can be cold-drawn at room temperature when relatively low strain rates are used but they become brittle as the strain rate is increased. It is thought that this is caused by a strain-rate-induced shift (to the right in Figure 19b) of the yield stress and brittle stress curves. This results in a temperature increase of the brittle–ductile transition.

It is known that the temperature at which the brittle–ductile transition occurs for a particular polymer is sensitive to both the structure of the polymer and the presence of surface flaws and notches. The temperature of the transition is generally raised by cross-linking and increasing the crystallinity. Both of these factors tend to increase the yield stress without affecting the brittle stress significantly. The addition of plasticizers to a polymer has the effect of reducing yield stress, thus lowering T_b. Plasticization is widely used in order to toughen polymers such as poly(vinyl chloride), which would otherwise have a tendency to be brittle at room temperature.

The presence of surface scratches, cracks or notches can have the effect of both reducing the tensile strength of the material and also increasing the temperature of the brittle–ductile transition. In this way the presence of a notch can cause a material to fail in a brittle manner at a temperature at which it would otherwise be ductile. As one might expect, this phenomenon can play havoc with any design calculations that assume the material to be ductile. This type of ''notch sensitivity'' is normally explained by examining the state of stress that exists at the root of the notch. When an overall uniaxial tensile stress is applied to the body there will be a complex state of triaxial stress at the tip of the crack or notch. This can cause a large increase in the stress of the material at the crack tip. As shown in Figure 20,[23] the brittle fracture stress will be unaffected and so the overall effect is to raise T_b. If the material is used between T_b for the bulk and T_b for the notched specimen, it will be prone to suffer from ''notch brittleness''.

4.5 Crazing

Crazing involves the formation of an intricate network of fibrils connecting the upper and lower surfaces of the craze. The craze itself forms at right angles to the applied stress. Shear yielding, on the other hand, involves molecular slip, usually at 45° to the applied stress, assuming uniaxial stress–strain relationships. If the polymer crazes, it usually fails after 1% or 2% extension and is said to be brittle. If it undergoes yielding, the

Figure 20 Schematic representation of the effect of notch on the ductile to brittle transition. (Reproduced by permission of John Wiley & Sons from I.M. Ward, D.W. Hadley, *An Introduction to the Mechanical Properties of Solid Polymers*, John Wiley & Sons, Chichester, 1996.)

Figure 21 Failure envelope for PMMA under biaxial stress at room temperature. (Reproduced by permission of the American Chemical Society from S.S. Sternstein, L. Ongchin, *Polym. Prepr.*, **10**(2), 1117 (1969).)

polymer usually can be stretched by at least 10% or 20% and is said to be ductile.

What criteria determine which mechanism will prevail? Polymers sometimes change from brittle to ductile on raising the temperature, as discussed earlier. Similarly, if the polymer is tested under compression, or under hydrostatic pressure, it tends to fail by shear yielding. Sternstein and Ongchin[38] studied the formation of crazes under biaxial stress conditions, and found that the stress conditions for crazing involved both principal stresses. They calculated the biaxial stress envelopes for PMMA. Figure 21 shows separately the envelopes for craze initiation and shear yielding. In the first quadrant of stress space, the crazing envelope is everywhere inside the shear yielding envelope, which implies that all combinations of tensile biaxial stress produce crazes prior to shear yielding. When the sample is under compression, third-quadrant yielding will always take place. In the second and fourth quadrants, the two envelopes intersect each other. Generally, the failure mechanism that takes place is the one requiring the lower stress. The 45° line running through the second and fourth quadrants represents pure shear deformation, marking the boundary between hydrostatic compression and hydrostatic tension. Crazing does not take place below this line because the pressure component of the stress tends to reduce rather than increase the volume.

The most physically acceptable explanation of Sternstein and Ongchin's results was proposed by Powden and Oxborough,[39] who suggested that crazing occurs when the extensional strain in any direction reaches a critical value. Unfortunately, there are several pieces of experimental evidence[40–42] that contradict this assumption, so there is still no completely satisfactory stress criterion for craze initiation.

There is, however, a theory for the growth of crazes, which is consistent with all the experimental evidence. Argon et al.[43] have proposed that the craze front advances by a meniscus instability mechanism in which craze tufts are produced by the repeated break-up of the concave air/polymer interface at the crack tip (as illustrated in Figure 22). A theoretical treatment of this model predicted that the steady-state craze velocity would relate to the five-sixths power of the maximum principal tensile stress, and support for this result was obtained from experimental results on polystyrene and PMMA.[43] More discussions on crazing can be found in Kausch.[44]

4.6 Fracture

Modern understanding of the fracture behavior of brittle materials stems from the seminal research of Griffith[45] on the brittle fracture of glass. The Griffith theory of fracture, which is the earliest statement of linear elastic fracture mechanics, has been applied extensively to the fracture of glass and metals, and more recently to polymers. The Griffith's criterion was initially conceived to describe the propagation of a crack in a perfectly elastic material at small elastic strains (hence, linear elastic). Subsequent work has shown that it is still applicable for situations including localized plastic deformation at the crack tip, which does not lead to general yielding in the specimen.

Griffith considered that fracture produces a new surface area and postulated that for fracture to occur the increase in energy required to produce the new surface must be balanced by a decrease in elastically stored energy.

Figure 22 Schematic diagram showing craze matter production by the mechanism of meniscus instability: (a) outline of a craze tip; (b) cross-section in the craze plane across craze matter tufts; (c, d) advance of the craze front by a completed period of interface convolution. (Reproduced by permission of Pergamon Press from A.S. Argon, J.C. Hannoosh, M.M. Salama, in *Fracture 1977*, Pergamon Press, Waterloo, Canada, 445, Vol. 1, 1977.)

To explain the large discrepancy between the measured strength of materials and those based on theoretical considerations, he proposed that the elastically stored energy is not distributed uniformly throughout the specimen but is concentrated in the neighborhood of small cracks. Fracture thus occurs due to the spreading of cracks that originate in pre-existing flaws.

Griffith calculated the change in elastically stored energy using a solution obtained by Inglis[46] for the problem of a plate pierced by a small elliptical crack. The plate is stressed at right angles to the major axis of the crack. He proposed that material fracture occurs when the stress reaches the break stress level as specified in Equation (43):

$$\sigma_b = \sqrt{\frac{2\gamma_s E^*}{\pi a}} \tag{43}$$

where γ_s is the intrinsic surface energy; a is the half-crack length; and E^* is the ''reduced modulus'', equal to Young's modulus E for a thin sheet in plane stress, and to $E/(1-\nu^2)$ for a thick sheet in plane strain. Here, ν is Poisson's ratio.

Equation (43) was specifically derived for a center-notched panel made of inorganic glasses for which viscoelastic motions are almost nonexistent. Experimentally determined values for the surface energy for polymers are, however, 100–1000 times the values calculated on the basis of bond breakage alone.[47,48] The increase is largely due to viscoelastic flow, which absorbs large amounts of energy. A more general form (Equation 44) was derived by Orowan,[49] who replaced γ_s with the term $\gamma_s + \gamma_p$, where γ_p accounts for the energy involved in plastic deformation:

$$\sigma_b = \sqrt{\frac{2(\gamma_s + \gamma_p)E^*}{\pi a}} \tag{44}$$

Irwin[50] considered the fracture of solid by studying the stress near the crack tip, which is given in the form shown by Equation (45):

$$\sigma = \frac{K}{\sqrt{2\pi r}} f(\theta) \tag{45}$$

where r is the distance to the crack tip and $f(\theta)$ is a function of the polar angle, θ (Figure 23). The value of Irwin's approach is that the stress field around the crack is identical in form for all types of loading situations normal

Figure 23 Definition of the coordinate axis ahead of a crack tip.

to the crack with the magnitude of the stresses (i.e. their intensity) determined by K, which is constant for given loads and geometry; K is called the stress intensity factor. As we approach the crack tip, the stresses become infinite in magnitude and r tends to zero, but the product $\sigma\sqrt{r}$ and hence K remain finite.

For an infinite sheet with a central crack of length $2a$ subjected to a uniform stress σ, it was shown (Equation 46) by Irwin that:

$$K = \sigma\sqrt{\pi a} \tag{46}$$

Irwin postulated that when σ reaches the fracture stress σ_b, K has a critical value given by Equation (47):

$$K_c = \sigma_b\sqrt{\pi a} \tag{47}$$

In linear elastic fracture mechanics it is useful also to consider the strain energy release rate, G, available for unit increase in crack length. It is assumed that fracture occurs when G reaches a critical value G_c, which is related to Griffith's surface energy as shown by Equation (48):

$$G = 2(\gamma_s + \gamma_p) \tag{48}$$

Comparison of Equations (44), (47) and (48) gives Equation (49):

$$K_c^2 = G_c E^* \tag{49}$$

There are three types of loading that a crack can experience, as shown in Figure 24. Mode I loading, where the principal load is applied normal to the crack plane, tends to open the crack. Mode II corresponds to in-plane shear loading and tends to slide one crack face with respect to the other. Mode III refers to out-of-plane shear. A cracked body can be loaded in any one of these modes, or a combination of two or three modes.

Both fracture toughness, K_c, and the critical energy release rate, G_c, are intrinsic material properties of polymers, like yielding strength and moduli. They form the central part of a great deal of the fracture and fatigue literature. Once the fracture toughness or critical energy release rate is known, it is possible to determine the value of the load that would cause failure. Values of K_c and G_c for some polymers are listed in Table 6.

Table 6 Young's modulus (E), fracture toughness (K_c), and critical energy release rate (G_c) for different polymers

Polymer	E (GPa)	K_c ($MN \cdot m\,m^{-2}$)	G_c ($kJ\,m^{-2}$)
Polystyrene	3.0	1.1	0.4
High-impact polystyrene	2.1	5.8	16
PMMA	3.0	1.2	0.5
Rubber-toughened PMMA	2.1	2.4	2.6
Epoxy resin	2.8	0.5	0.1
Rubber-toughened epoxy resin	2.4	2.2	2.0
Silica-filled epoxy resin	7.5	1.4	0.3

4.7 The Tearing of Rubbers: Extension of Griffith Theory

Rivlin and Thomas[51] and Thomas[52] recognized that the reduction in elastically stored energy due to crack propagation may be balanced by changes in energy other than that due to an increase in surface energy. Their approach was to define a quantity termed the "tearing energy", which is the energy expended per unit thickness per unit increase in crack length. The tearing energy includes surface energy, energy dissipated in plastic flow processes and energy dissipated irreversibly in viscoelastic processes. If all these changes in energy are proportional to the increase in crack length and are primarily determined by the state of deformation in the neighborhood of the tip of the crack, the total energy will still be independent of the shape of the test piece and the manner in which the deforming forces are applied.

In formal mathematical terms,[23] if the crack increases in length by an amount da, an amount of work TB da must be done, where T is the tearing energy per unit area

Figure 24 The three modes of loading that can be applied to a crack.

Figure 25 The standard "trouser tear" experiment.

and B is the thickness of the sheet. If no external work is due, this can be equated to the change in elastically stored energy, U, according to Equation (50):

$$-\left(\frac{\partial U}{\partial a}\right)_d = TB \tag{50}$$

The suffix d indicates that differentiation is carried out under conditions of constant displacement of the parts of the boundary that are not force-free. In Equation (50), T is defined for unit thickness of specimen. As in the case of glassy polymers, T is not to be interpreted as a surface-free energy, but involves the total deformation in the crack tip region as the crack propagates.

The so-called "trouser tear" experiment shown in Figure 25 is a particularly simple case where the equation can be evaluated immediately. After making a uniform cut in a rubber sheet the sample is subjected to tear under the applied force F. The stress distribution at the tip of the tear is complex but, provided that the legs are long, it is independent of the depth of the tear.

If the sample tears a distance da under the force F, and changes in extension of the material between the tip of the tear and the legs are ignored, the work done is given by $\Delta W = 2F\Delta a$. Because the tearing energy $T = \Delta W/B\ \Delta a$, $T = 2F/B$ and can be measured easily.

Rivlin and Thomas[51] found that two characteristic tearing energies could be defined, one for very slow rates of tearing ($T = 37\,\mathrm{kJ\,m^{-2}}$) and one for catastrophic growth ($T = 130\,\mathrm{kJ\,m^{-2}}$), and that both of these quantities were independent of the shape of the specimen.

The tearing energy is the energy required to extend the rubber to its maximum elongation and does not relate directly to tensile strength, but depends on the shape of the stress–strain curve together with the viscoelastic nature of the rubber. For example, we may contrast two different rubbers, the first possessing a high tensile strength but a very low elongation to fracture and very low viscoelastic losses, and the second possessing a low tensile strength but a high elongation to fracture and high viscoelastic losses. In spite of its comparatively low tensile strength, the second rubber may still possess a higher tearing energy.

4.8 Temperature and Loading Rate Effects: Viscoelastic Rupture of Elastomers

When simple cross-linked elastomers are stretched and held at high elongation, they will undergo a smooth relaxation period followed by sudden failure. This sequence is depicted in Figure 26 for poly(styrene–co-butadiene) rubber.[22,53–55]

Our interest lies in the loci of failure points as a function of temperature. The family of curves of stress to break σ_b at various temperatures is plotted schematically in Figure 27(a).[53] Use may be made of the time–temperature superposition principle and the WLF equation to construct a master curve, as shown in Figure 27(b).

Any amorphous polymer that is stretched undergoes some orientation of polymer segments. In this oriented state, crystallization may occur. This will increase the effective number of cross-links. If crystallization does not occur, the behavior of the sample to rupture may be described by the same equation as that for small deformations. The mechanical test most often used is one that measures stress at a constant strain rate. The ultimate tensile stress and strain at rupture vary with temperature and rate of strain. For a cross-linked unfilled rubber, which does not crystallize on stretching, the shift factors of the WLF equation (see Equation 51) allow a reasonable superposition over a wide range of conditions. In Figure 28, the stress at break σ_b is multiplied by the ratio of a reference temperature ($T_s = 263\,\mathrm{K}$) to the test temperature in accordance with the theory of rubber elasticity. The shift factors a_T, used to multiply the rate of extension R (meters per meter per second), is given

Figure 26 Stress relaxation of a cross-linked poly(styrene–co-butadiene) rubber (at 1.7 °C) at elongation from 350 to 525%. Solid points indicate rupture; the dashed line gives the ultimate strength. (Reproduced by permission of the Society of Plastics Engineers from K.W. Scott, *Polym. Eng. Sci.*, **7**, 158 (1967).)

Figure 27 (a) The loci of failure point for a cross-linked poly(styrene–co-butadiene) rubber obtained as the temperature is increased from T_1 to T_5 through the glass–rubber transition. (b) Master curve of reduced stress to break vs reduced time to break for cross-linked poly(styrene–co-butadiene) rubber. (Reproduced by permission of the Society of Plastics Engineers from K.W. Scott, *Polym. Eng. Sci.*, **7**, 158 (1967).)

approximately by the WLF equation in modified form, because T_s is not T_g (Figure 29):

$$\log a_T = -\frac{8.86(T - T_s)}{101.6 + T - T_s} \qquad (51)$$

A similar reduced curve can be produced for the strain at break ε_b (Figure 30) using the same shift factors.

4.9 Fatigue

The case of creep in a polymer subjected to a constant stress has already been mentioned before. Cyclic or repeated stresses are also important in actual service, and give rise to the phenomenon of fatigue.[56–61]

Materials frequently fail by fatigue caused by the cyclic application of stresses that are below that required to cause yield or fracture when a continuously rising stress is applied. Thousands or tens of thousands of cycles may elapse with little appearing to happen. This is followed by catastrophic failure. In some cases a so-called ''endurance limit'' is observed below which fatigue failure never occurs (see Figure 31[61]). The endurance limit of PMMA shown in Figure 31 is about 2700 psi, below which no fatigue failure is observed. On the other hand, Nylon 6 does not have an endurance limit. In general, the higher the stress, or the higher the temperature, the shorter the lifetime. In terms of molecular processes, fatigue failure involves two mechanisms: weakening by adiabatic heating due to the presence of energy-dissipating modes of relaxation, and mechanical initiation and propagation of a crack. The former mechanism is dominant at high frequencies.[61] and the latter at low frequencies.[56,59]

Hertzberg and Manson[60] have identified several important molecular aspects of the fatigue process:

- High molecular weights and narrow molecular-weight distributions are generally more fatigue resistant.
- Chemical changes such as bond breakage are to be avoided or minimized.
- Elastic, inelastic, and viscoelastic deformation of the chains is desired. These motions absorb energy and tend to prevent crack growth, provided that the sample does not heat up excessively.
- Morphological changes such as drawing, orientation, and crystallization also absorb energy and are desired.
- Samples undergoing cyclic stressing at frequencies and temperatures near the glass transition temperature or secondary transitions will tend to heat up more than otherwise, causing softening or degradation.
- Adiabatic heating caused by such hysteretic effects is clearly undesirable.
- Inhomogeneous deformations, such as crazing and shear banding, absorb energy and are desired. It is especially desirous to have shear banding occur before crazing, i.e. the former mechanism should have a lower free energy of initiation.

Of course, several of these factors may be operative simultaneously.

The presence of a crack can significantly reduce the strength of a polymer due to brittle fracture as already discussed in section 4.6. A common situation is that a small flaw that was initially present develops into a crack and then grows until it reaches the critical size for brittle fracture. Crack growth can be caused by cyclic loading, a behavior called fatigue crack growth. Analysis of fatigue crack growth can be done using the stress intensity concept of fracture mechanics. Figure 32 is a schematic log–log plot of da/dN versus ΔK, which illustrates typical fatigue crack growth behavior. Here, a is the crack length, N is the number of cycles, and ΔK is the range of the stress intensity factor, i.e. the difference between the maximum stress intensity factor K_{max} and the minimum stress intensity factor K_{min} during fatigue.

Figure 28 Variation of the tensile strength for a cross-linked poly(styrene–co-butadiene) rubber with reduced strain rate. Reference temperature is 263 K. (Reproduced by permission of John Wiley & Sons from T.L. Smith, *J. Polym. Sci.*, **32**, 99 (1958).)

Figure 29 Experimental values of shift factor a_T from experiment and from a WLF-type equation in which the reference temperature is 263 K. (Reproduced by permission of John Wiley & Sons from T.L. Smith, *J. Polym. Sci.*, **32**, 99 (1958).)

The sigmoidal curve contains three distinct regions. At intermediate ΔK values the curve is linear, but the crack growth rate deviates from the linear trend at high and low ΔK levels. In the former case, the crack growth rate accelerates as K_{max} approaches K_c, the fracture toughness of the material. At the other extreme, da/dN approaches zero at a threshold ΔK.

The linear region of the log–log plot in Figure 32 can be described by the power law shown in Equation (52):

$$\frac{da}{dN} = A(\Delta K)^m \tag{52}$$

where a is the crack length, N is the number of cycles, ΔK is the range of the stress intensity factor (i.e. $K_{max} - K_{min}$), and A and m are constants that depend on the material and test conditions.

Equation (52) is also the most general form of the law proposed by Paris[62] and Paris and Erdogen[63] for predicting fatigue crack growth rates in metals. The general situation for glassy polymers is illustrated with some typical results shown in Figure 33,[64] where c, instead of a, is used for the crack length. A comprehensive review of the application of the Paris equation and its modified form to the fatigue behavior of polymers has been given by Manson and Hertzberg.[60]

4.10 Effects of Molecular Weight and Crystallinity

The molecular weight of the polymer has significant effects on mechanical properties. At very low molecular weight, a polymer is a viscous liquid if the T_g is below

Figure 30 Variation of the break strain for a cross-linked poly(styrene–co-butadiene) rubber with reduced strain rate. Reference temperature is 263 K. (Reproduced by permission of John Wiley & Sons from T.L. Smith, *J. Polym. Sci.*, **32**, 99 (1958).)

Figure 32 Typical fatigue crack growth behavior.

ambient temperature. At higher molecular weight, a polymer may become an elastomer, having low strength and a high elongation to break. Above a molecular weight of about 10^5, polymers become entangled enough to show true rubbery behavior above T_g and to exhibit a greatly increased elongation to break. If the polymer is of very low molecular weight and the T_g is higher than ambient temperature, the material is brittle. Hence, molecular entanglement must take place before the polymer can become strong enough to sustain the load. It is also true that chain ends act as imperfections in the polymer network that can adversely affect the strength properties. These same ends have little effect on the elastic moduli.

Nunes et al.[65] have reviewed the literature on polymer mechanical properties as a function of molecular weight and molecular weight distribution published from 1972 to 1982. Thermal properties, stress–strain properties, impact, fracture, fatigue, creep, stress relaxation, and cracking and crazing were examined for a wide variety of homopolymers and a limited number of copolymers. In general, mechanical properties increase as the molecular weight increases. Above some limiting molecular weight the mechanical property is usually unaffected. Although much work has been done to describe the effects of molecular weight on mechanical properties, little

Figure 33 Fatigue crack growth data for a vinyl urethane polymer. (Reproduced by permission of Kluwer Academic Publishers from J.S. Harris, I.M. Ward, *J. Mater. Sci.*, **8**, 1655 (1973).)

quantitative correlation exists. The available equations to predict such properties as cracking and crazing, T_g, T_m and tensile strength from molecular characteristics were discussed in detail by Nunes et al.[65] A more quantitative description incorporating a wider range of mechanical properties would be more useful. This would facilitate the use of the vast amount of information available and enable it to be applied more readily to new polymer systems.

Crystallization improves the strength and modulus of polymers by reducing the degree of molecular randomization.[66] The basic crystal structure of a semicrystalline polymer consists of chain-folded lamella radiating outward from a nucleation site to form a spherulite. A molecular chain can exist in more than one lamella and more than one spherulite. The intracrystalline and intercrystalline molecular segments are called tie molecules. The molecules provide the load-bearing strength of the bulk polymer. High-molecular-weight polymers have more tie molecules and consequently higher strengths. The modulus of a polymer, however, is not strongly affected by molecular weight.

Orienting semicrystalline polymers further improves the strength and modulus in the orientation direction. Orientation is used to produce a high degree of crystal alignment in high-strength nylon, poly(ethylene terephthalate) and polypropylene textile fibers. The crystal structure in an oriented fiber still contains regions between the chain folds that cannot carry a load. This reduces the overall strength and modulus of the fiber. When the crystal segments are lengthened there are fewer chain fold defects, resulting in a stronger and stiffer fiber. High-density polyethylene has an ultimate strength of 19 GPa and a modulus of 300 GPa because its backbone is the very strong carbon–carbon bond.[67] The primary reason why these high mechanical properties are not achieved is that thermodynamic considerations favor the formation of the spherulitic rather than extended crystal structures as the polymer is quenched from the melt.

Orientation of a semicrystalline polymer below its melting point produces extended chain crystals having fewer chain folds and defects. Because of the high ultimate strength of the carbon–carbon bond, a fully aligned polymer has a very high strength and modulus. There are a number of solid-state processes capable of producing this type of crystal structure realignment. Melt processing is the most common polymer processing technique, because it allows high rates of production, has modest power requirements, and is capable of producing a wide variety of product shapes. Highly oriented crystal structures can, however, only be formed by rearranging the spherulitic crystal structure below the melting point of the polymer. There are several solid-state processing techniques capable of producing the extended chain crystals for the production of very-high-modulus polymers: drawing, extrusion, rolling, and high-pressure crystallization. A review of these techniques with emphasis on the process parameters and properties of the resulting materials has been given by Bigg.[68]

5 POLYMER BLENDS AND COMPOSITES

In this article, polymer blends are defined as combinations of two or more kinds of polymers, and composites are defined as systems combining two or more materials that are mutually insoluble by mixing or bonding them in such a way that each maintains its integrity. Polymer blends and composites can be tailored to meet special needs such as high strength and stiffness combined with light weight. The resulting high-performance materials are being increasingly used in aircraft, space, and defense applications. More economical composites, such as glass-reinforced plastics, are continually finding new uses in a wide range of products, such as automotive components, boat hulls, sports equipment, and furniture.

Polymers are often thought of as being mechanically weak and their mechanical properties have consequently been somewhat ignored in the past. With the increasing use of polymer blends and composites as major load-bearing components, however, an understanding of their mechanical properties and performance is becoming an essential part of engineering design.

Polymer blends and composites display a broad gamut of behavior, ranging from toughened elastomers through

impact-resistant plastics to fiber-reinforced thermosets and polymer-impregnated concrete. Such materials are of practical importance because their unique multiphased structure often allows for nonlinear and synergistic behavior. In this respect, polymer blends and composites are useful because of their complexity, not in spite of it. Blends and composites are toughened because many modes of resistance to failure are available.

A tremendous amount of research and development has been conducted in the past three decades on the mechanical properties of polymer blends and composites because of their importance for structural applications, and the complicated nature of nonlinear and synergistic effects of phases in controlling their mechanical performance. The flood of important research in this area has resulted in many symposia, edited collections of papers, reviews and contributions to scientific journals.[69–76] A systematic approach has been established from which the mechanical performance of a composite system, such as stiffness, strength, and failure, can be accurately predicted in a closed form or a semiclosed form based on the mechanical properties of each constituent and the interface.[77–83] A comprehensive review of the subject of composites in six print volumes has been published by Pergamon Press.[84]

5.1 Polymer Blends

The principal methods of preparing polymer blends include mechanical blending, graft copolymerization, block copolymerization, and interpenetration of two networks. The last two are often considered as subgroups of the graft method.

5.1.1 Mechanical Blends

Polymer blends may be defined as intimate mixtures of two or more kinds of polymers, with no covalent bonds between them. Historically, the oldest and simplest method involves mechanical blending, where a plastic and a noncross-linked elastomer are blended either on open rolls or through extruders.[85] Materials prepared in this manner usually contain several percent of elastomer dispersed in a plastic matrix.

In simple mechanical blends the plastic component usually predominates, with the dispersed elastomer having dimensions of the order of several micrometers. The shear action of mechanical blending also generates free radicals through polymer degradation reactions. The free radicals thus induced by mechanochemical action subsequently react to form a small number of true chemical grafts between the two components. The quantity and importance of such grafted material obviously depend on the exact mode of blending.[86] Significant improvements in impact resistance and toughness are usually noted for such blends even in cases where no particular amount of grafting is noted.

5.1.2 Graft Copolymers

Further improvement in mechanical behavior can be obtained by graft copolymerization. In the graft copolymerization method[87] the first polymer (usually the rubber) portion is dissolved in the plastic monomer, and polymerization is effected. During the polymerization, some or the entire second polymer becomes joined to the first. Often the polymerization is carried out with stirring, to bring about phase inversion. This results in a much finer dispersion of the rubber phase, and a far more complex morphology. Polymer blends and grafts designed for impact resistance have been discussed in detail by Manson and Sperling.[88]

5.1.3 Block Copolymers

In block copolymers, the individual components are joined at their ends. Block copolymers have been synthesized by several methods, but perhaps the most elegant procedure follows the ''living polymer'' anionic polymerization process.[89] The unusual features of this reaction include simultaneous nucleation and uniform growth rates of all chains, and lack of termination reactions. After exhaustion of a first monomer the polymer chains remain alive, and addition of a second monomer results in a block copolymer of the form shown in Equation (53):

$$\mathrm{A} - (\mathrm{A})_{n-2} - \mathrm{A} - \mathrm{B} - (\mathrm{B})_{m-2} - \mathrm{B} \qquad (53)$$

where n and m are the degrees of polymerization of the A- and B-mer units, respectively. More blocks can be added in the same manner, if desired. Block copolymerization results in extremely fine phases, called domains, in the form of characteristic spheres, cylinders, or lamellae. The size and shape of the phase depend on composition. An important class of block copolymers is made up of the triblock ABA thermoplastic elastomers[90] discussed by Manson and Sperling.[88]

5.1.4 Interpenetrating Polymer Networks

This novel class of polymers, together with simultaneous interpenetrating networks (SINs) and interpenetrating elastomeric networks (IENs),[91] form another important class of two-phase polymer systems. Interpenetrating polymer networks (IPNs) can be formed[92] by preparing a cross-linked polymer network, swelling in a second monomer together with activator and cross-linking agent, and polymerizing in situ. This second reaction forms

a cross-linked polymeric network that interpenetrates the first network. A SIN differs from an IPN in that both networks are formed more or less simultaneously. An example might involve concurrent noninterfering addition and condensation polymerizations, each reaction having appropriate cross-linking agents.[93] IPNs and SINs also form distinct and characteristic domain-type structures, with the restriction that both components must be continuous throughout the macroscopic mass. IENs are prepared by mixing and coagulating two different kinds of polymeric latexes, followed by a single cross-linking reaction. The result is a three-dimensional mosaic structure. The IPNs and IENs have been discussed by Manson and Sperling.[88]

5.2 Polymer Composites

Composites can be placed into three categories – particulate, fiber, and laminar – based on the shapes of the reinforcement materials.

5.2.1 Particulate Composites

Many engineering polymers that contain fillers and extenders are particulate composites. A classic example is carbon black in vulcanized rubber. Carbon black consists of tiny carbon spheroids only 5–500 nm in diameter. The carbon black improves the strength, stiffness, hardness, wear resistance, and heat resistance of the rubber.

Extenders, such as calcium carbonate, solid glass spheres, and various clays, are added so that a smaller amount of the more expensive polymer is required. The extenders may stiffen the polymer, increase the hardness and wear resistance, increase thermal conductivity, or improve resistance to creep. Strength and ductility, however, normally decrease. Introducing hollow glass spheres may impart the same changes in properties while significantly reducing the weight of the composite.

5.2.2 Fibrous Composites

Strong and stiff fibers can be made from ceramic materials that are difficult to use as structural materials in bulk form. Examples include glass, graphite (carbon), boron, and silicon carbide. When fibers of these materials are embedded in a matrix of a ductile material, such as a polymer, the resulting composite can be strong, stiff, and tough. The fibers carry most of the stress, whereas the matrix holds them in place. Good adhesion between fibers and matrix is important because this allows the matrix to carry the stress from one fiber to another. Fiber diameters are typically in the size range 1–100 μm. Fibers are used in composites in a variety of different configurations. Short, randomly oriented fibers result in a composite that has similar properties in all directions. Chopped glass fibers used to reinforce thermoplastics are of this type. Whiskers are a special class of short fiber that consist of tiny elongated single crystals that are very strong because they are dislocation free. Diameters are 1–10 μm or smaller, and lengths are 10–100 times larger than the diameter.

Long fibers can be woven into a cloth or made into a mat of intertwined strands. Glass fibers in both of these configurations are used with polyester resins to make common fiberglass. High-performance composites are often made using long, straight, continuous fibers. Continuous fibers all oriented in a single direction provide maximum strength and stiffness parallel to the fibers. Because such a material is weak if stressed in the transverse direction, several thin layers with different fiber orientations are usually stacked into a laminate. For example, composites with a thermosetting plastic matrix, often epoxy, are assembled in this manner. This is done using partially cured sheets, which are called prepregs because they have been previously impregnated with the epoxy resin. Appropriate heat and pressure are applied to complete the cross-linking reaction, while at the same time bonding the layers into a solid laminate. Fibers commonly used in this manner with an epoxy matrix include glass, graphite, boron, and the aramid polymer Kevlar.

5.2.3 Laminated Composites

A material made by combining layers is called a laminate. The layers may differ as to the fiber orientation, or they may consist of different materials. As already noted, unidirectional composite sheets are frequently laminated. The recently developed aramid–aluminum laminate has layers of an aluminum alloy and a composite with unidirectional Kevlar fibers in an epoxy matrix.

Where stiffness in bending is needed along with light weight, layers of a strong and stiff material may be placed on either side of a lightweight core. Such sandwich materials include aluminum or fibrous composite sheets bonded on each side of a core that is made of a stiff foam. Another possibility is a core made of a honeycomb of aluminum or other material.

5.3 Mechanical Behavior of Rubber-toughened Polymers

The incorporation of rubber particles into a brittle polymer has a profound effect upon the mechanical properties, as shown from the stress–strain curves in Figures 34 and 35, and the discussion provided by Young and Lovell.[21] Included in Figure 34 are the stress–strain curves for polystyrene and high-impact polystyrene (HIPS), which is a blend of polystyrene and polybutadiene. The curve for polystyrene shows

Figure 34 Stress–strain curves for polystyrene and HIPS. (Reproduced by permission of Stanley Thornes Publishers from R.J. Young, P.A. Lovell, *Introduction to Polymers*, 2nd edition, Chapman & Hall, London, 1995.)

Figure 35 Stress–strain curves for RTPMMA showing the effect of the weight fraction of rubber particles w_p. (Reproduced by permission of Stanley Thornes Publishers from R.J. Young, P.A. Lovell, *Introduction to Polymers*, 2nd edition, Chapman & Hall, London, 1995.)

brittle behavior. The inclusion of the rubbery phase causes the material to undergo yield and the sample to deform plastically to about 40% strain before eventually fracturing. The plastic deformation is accompanied by "stress-whitening", whereby the necked region becomes white in appearance during deformation. As will be explained later, this is due to the formation of a large number of crazes around the rubber particles in the material.

Figure 35 shows a series of stress–strain curves for samples of rubber-toughened poly(methyl methacrylate) (RTPMMA) containing different weight fractions, w_f, of toughening particles. It can be seen that PMMA is relatively brittle, but following the addition of rubbery particles the material is able to undergo yield and deform plastically. A maximum elongation of over 45% is obtained for $w_f = 0.35$. It is found that, as with HIPS, stress-whitening is obtained following yield. In the case of RTPMMA this is thought to be due to the particles undergoing voiding rather than crazing taking place. The reduction in elongation for $w_f > 0.35$ is because at high values of w_f the particles become so close that they touch and interact with each other and thereby reduce the efficiency of toughening.

As well as toughening thermoplastics such as polystyrene and PMMA, it is also possible to toughen brittle network polymers such as epoxy resins by the addition of a rubbery second phase. Figure 36 shows the effect of the volume fraction of rubber particles, V_p, upon the fracture energy release rate, G_c, for a rubber-toughened epoxy resin.[94] The samples were prepared by the addition of 8.7% by weight of a carboxyl-terminated poly(butadiene–co-acrylonitrile) rubber to the epoxy prepolymer and curing agent. The rubber is soluble in the prepolymer but precipitates in the form of particles as the resin increases in molar mass during curing. The variation of V_p in Figure 36 was obtained by varying the cure conditions employed. Although the weight of rubber used in each case was constant, it can be seen from Figure 36 that it is the volume fraction of rubber precipitated in the form of particles that controls the toughness of the material. It should be noted that the rubber employed had reactive carboxylic acid end-groups that are capable of reacting with the epoxy prepolymer, thus ensuring a

Figure 36 Dependence of G_c on rubber phase volume fraction for a rubber-toughened epoxy resin. (Reproduced by permission of Elsevier from C.B. Bucknall, M. Yoshi, *Br. Polym. J.*, **10**, 53 (1978).)

strong interface between the rubber particles and the epoxy matrix.

Both crazing and shear yielding involve the absorption of energy, and most methods of toughening brittle polymers involve modifying the polymer such that controlled high levels of crazing or shear yielding are able to take place. The second-phase spherical particles of the rubber have a Young's modulus about three orders of magnitude lower than that of the glassy matrix (Table 7[95]). This leads to a stress concentration at the equators of the particles during mechanical deformation, which is similar to the stress concentration found around holes and notches in plates. The presence of the stress concentration can lead to shear yielding or crazing around every particle and hence throughout a large volume of material rather than just at the crack tip. The polymer, therefore, absorbs a large amount of energy during deformation and is toughened.

The exact mechanisms of deformation around the rubber particles depend upon the type of polymer and the conditions of testing (rate and temperature). The structure of rubber-toughened polymers is generally visualized by transmission electron microscopic examination of thin microtomed sections. For HIPS, relatively large crazes emanate from the equators of the rubber particles. In the case of RTPMMA a large number of smaller particles generally are employed. The particles are typically of the order of 0.2–0.3 μm in diameter and have a complex morphology. It is thought that the particles in the RTPMMA toughen the material by inducing the formation of shear bands around the particles. Because they do not lead to cavitation in the matrix or a change in polymer density, they cannot be seen by electron microscopy. The material does, however, undergo some stress-whitening, which is thought to be caused by some limited cavitation within the particles.

A further insight into the deformation mechanisms that take place in rubber-toughened polymers can be obtained by measuring the change in specimen volume during deformation. In the case of HIPS, there is a significant increase in specimen volume. Plastic deformation normally occurs at constant volume and so this large increase in volume shows that crazing takes place on a large scale during deformation of the material. The behavior of HIPS can be contrasted with that of RTPMMA, for which there is no change in specimen volume during deformation. This is further confirmation that the toughening mechanism in the RTPMMA is shear yielding because shear yielding takes place at approximately constant volume.

More recently, Lovell et al.[96] have studied the effects of acrylic-matrix properties, toughening-particle composition, morphology, size, and level of inclusion on mechanical properties and fracture behavior of a range of rubber-toughened acrylic polymers.

Table 7 Typical values of Young's modulus (E) and break strength (σ_f) at room temperature and moderate testing rate

Polymer	E (Pa)	σ_f (MPa)
Rubber	$\sim 10^6$	~ 10
Semicrystalline polymer, above T_g	$\sim 10^8$	~ 30
Semicrystalline polymer, below T_g	$\sim 10^9$	~ 50
Glassy polymer	$\sim 10^9$	~ 70
Semicrystalline polymer fiber	$\sim 10^{10}$	~ 500
Polymer single-crystal fiber	$\sim 10^{11}$	~ 2000

5.4 Polymer Thin Films with Fillers

Some polymers and polymer thin films contain fillers (particulate) for a purpose other than mechanical reinforcement. In fact, they may degrade the mechanical properties. One example is photographic film, most of which consist of gelatin layers containing fillers.[97] Fillers such as silver halide crystals and coupler/coupler solvent droplets are in the photographic emulsions. Couplers are organics that react with the oxidized developer during photoprocessing to form dyes of various colors.

Although the needs for understanding the effects of fillers on mechanical behavior of polymer thin films and coatings are slowly being recognized, experimental determination remains difficult. Some polymer films are too thin and well adhered to the substrate to be readily available as a single layer for testing. Some of these additives, such as the coupler/coupler solvent dispersions or latex, are prepared in solutions and could not be extracted easily to form solid films for evaluation. Thus, analysis by means of analytical models becomes indispensable in evaluating the mechanical testing results of filler-containing films and coatings to understand the filler effects. These models may also be applied to study the effects of filler size, shape, concentration, and mechanical behavior on coating properties and, thus, potentially be utilized to optimize and design the filled system for mechanical strength without many costly experiments.

The approaches to filler effects on polymers may be divided into three categories: empirical approach, kinetic approach, and micromechanical approach. The empirical approach is based on interpolation of certain experimental data for specific filler/polymer systems. Such a formulation usually involves some curve-fitting parameters, but their physical implications are generally vague. The accuracy of the empirical approach may be very poor, especially when the formulation is used in a material system that is quite different from the one used to establish the model.

The kinetic approach considers molecular structures, network chains of filler, polymer and filler-to-polymer

linkages, and provides a rigorous treatment of mechanical (physical) properties of filler/polymer systems. In the case of filler-reinforced elastomers, kinetic theory predicts that the equilibrium stress in an unfilled vulcanizate is proportional to the number of elastically effective network chains supporting the load.[2] This number depends on the primary molecular weight of the rubber, the number of cross-links forming between the network, and the number of chain entanglements isolated between these cross-links.[98,99] For a swollen rubber a simple method exists for estimating the number of network chains using the concept of equilibrium swelling.[100]

The numerous difficulties encountered in the application of kinetic theory are discussed by Bueche.[101] They may be summed up by stating that a truly rigorous extension of the kinetic theory to filled polymers is still lacking. The result is that estimates of the number of filler-to-polymer linkages based on modulus considerations can be regarded as realistic only within an order of magnitude.[102] Thus, although the basic idea of this approach is undoubtedly sound, it sometimes does not lead to very useful results.[102]

The micromechanical approach is a continuum mechanics-based approach that utilizes a level larger than molecular scale but is still small enough to represent filler–filler interactions and filler–polymer interaction. It is based on the premise that the mechanical properties of a filled polymer are the result of the mechanical and synergistic effects of the filler, the host polymer, and the interactions through interfacial bonding. The emphasis is placed on the mechanics involving filler, host polymer, and interface because the mechanical properties of the filled system are the quantities of interest. The filler-to-polymer linkages come into play through mechanics representation of adhesion in the micromechanics treatment.

5.4.1 Moduli of Polymer Composites

The exact theoretical evaluation of effective elastic properties of a filled polymer film is, in general, very difficult because it requires a precise knowledge of the stress and strain fields everywhere in the filled polymer film. Therefore, many micromechanics-based models have been introduced to make such a problem mathematically tractable. The simplifying assumptions used in these models may, however, give rise to considerable differences in the predictions, as shown by Christensen[103] and Christensen et al.[104] The methods that are widely used include the self-consistent method,[105–107] the differential scheme,[108] the Mori–Tanaka method,[109,110] the generalized self-consistent method,[111,112] and the composite cylinder assemblage model.[113]

Gao and Tsou[114] have formulated expressions for moduli of a material containing three-dimensional, randomly distributed, ellipsoidal inclusions (fillers). When the inclusions are spherical, these expressions are simplified as (Equations 54–56):

$$K_c = K_m + \frac{V_f(K_f - K_m)}{(1 - V_f)\alpha(K_f - K_m) + K_m} K_m \tag{54}$$

$$G_c = G_m + \frac{V_f(G_f - G_m)}{(1 - V_f)\beta(G_f - G_m) + G_m} G_m \tag{55}$$

where

$$\alpha = \frac{1}{3}\frac{(1 + \nu_m)}{(1 - \nu_m)} \qquad \beta = \frac{2}{15}\frac{(4 - 5\nu_m)}{(1 - \nu_m)} \tag{56}$$

V_f is the volume fraction of the fillers; the subscripts, "c", "f", and "m" denote quantities related to the filled polymer film (composite), the filler, and the matrix material, respectively. The bulk and shear moduli, K and G, are related to Young's modulus and Poisson's ratio through conventional relationships for moduli of isotropic materials given in Table 1.

There are various models in the literature for the prediction of the moduli of polymers containing fillers.[115] Most of them work well for a low volume fraction of fillers, whereas others require that the stiffness of the fillers be much lower or much higher than that of the matrix. The Voigt model is based on the rule of mixture formula (Equation 57):

$$E_c = E_m(1 - V_f) + E_f V_f \tag{57}$$

It assumes that the monomer and polymer molecules are lined up in series and experience the same stress. The Reuss model has the form of Equation (58):

$$\frac{1}{E_c} = \frac{(1 - V_f)}{E_m} + \frac{V_f}{E_f} \tag{58}$$

which assumes that all molecules are lined up in parallel and so experience the same strain. For fiber-reinforced composites, Equations (57) and (58) can be used to determine the composite moduli in fiber and transverse direction, respectively.[23] The effect of particle shape on the moduli of filled polymers has been reviewed by Chow.[116]

The situation is considerably more complicated with more random structures such as spherulitic polymers. The measured modulus of such a structure is an average of that of the crystalline and amorphous regions. Even when it is assumed that the amorphous material is isotropic, there are problems in determining how to estimate the effective average modulus of the crystals and how to combine this with the modulus of the amorphous material to give an overall modulus for a polymer sample. This latter problem can be overcome by extrapolating

measurements of modulus as a function of crystallinity to 100% crystallinity.[21] The structure of such a material can be thought of as a randomly oriented polycrystalline structure not unlike a polycrystalline metal. The Reuss and Voigt models can again be applied with their respective assumptions of uniform stress and uniform strain.

5.4.2 *Strength of Polymer Composites*

Despite its great practical importance, the dependence of the strength of polymer films containing fillers on the filler's properties is not as clearly understood as that of the moduli of such materials. The fracture and failure processes of filled polymers are extremely complicated. This is due not only to the existence of local inhomogeneity in the materials, but also to several possible failure modes that are closely related to interfacial strength, dewetting, stress concentration at the interface, and relative brittle or ductile nature of the filler and the matrix materials. An approach often used to predict the strength of random short-fiber composites utilizes a laminate-analysis procedure. In this approach, the strength of an isotropic laminate constructed from unidirectional plies (with fiber aligned in one direction) is used to approximate the strength of random-fiber composites. Kardos[117] compared experimental results obtained by Lavengood[118] with the predictions of isotropic laminate analogy calculation. For the purpose of calculating ultimate strength, a modified maximum strain theory of failure was applied. Very little work can be found for strength prediction for composites containing cubic, spherical or elliptical fillers.

Unlike the stiffness of a material, the strength is a property that depends directly on local stress concentration and ductility of the material, and therefore is extremely difficult to predict. The addition of fillers can significantly change the mechanical characteristics of the material. The ability to predict the break strength and break strain is very critical for many polymer films to determine the physical performance of the materials. In most cases, the films are too thin to be tested mechanically for break strength and break strain.

Using the energy consideration, Gao and Tsou[114] have proposed the break stress and strain formulations shown in Equations (59) and (60):

$$\tilde{\sigma}_c = \left(\frac{E_c}{E_m}\right)^{\tau} \tilde{\sigma}_m \tag{59}$$

$$\tilde{\varepsilon}_c = \left(\frac{E_m}{E_c}\right)^{w} \tilde{\varepsilon}_m \tag{60}$$

where E_c and E_m are the Young's modulus of the filled polymer composite and matrix polymer, respectively; ε_c and σ_c are the average strain and stress of the composite in the loading direction, respectively; and $\tilde{\sigma}_m$ and $\tilde{\varepsilon}_m$ are the break stress and break strain of the matrix material, respectively. The parameters τ and w are to be determined from experimental data.

The material system used in the tests for validation of the composite modulus model is strippable 20-μm thick coatings of gelatin containing various concentrations of tricresyl phosphate solvent droplets. Uniaxial tensile properties of these coatings were measured using a SYNTEC tensile tester with specimens of dimension 15 mm × 100 mm at 21 °C and 50% relative humidity. The strain rate was 0.5 in. in.$^{-1}$ min^{-1}. The modulus and break strength of the pure gelatin (without fillers)

Figure 37 Comparison of the present model with experimental data of Young's modulus.

Figure 38 Comparison between the proposed model (solid line) and experimental data (dots) for the break strength of a gelatin/latex system.

were measured as 5.38 GPa and 101.97 MPa, respectively. The average size of the droplets was measured as 0.55 μm by confocal microscopy and transmission electron microscopy.

In Figure 37, the experimental data for the 20-μm-thick coatings of gelatin containing various concentrations of tricresyl phosphate solvent droplets are compared with Equation (55). The predictions for tensile break strength from the proposed model (Equation 59) with $\tau = 0.5$ are compared with experimental data for gelatin films containing various volume fractions of latex filler (Figure 38). The latex filler is poly(*n*-butylacrylate–co-2-aminoethyl methacrylate hydrochloride–co-2-hydroxyethyl methacrylate) (60 : 30 : 10) made by emulsion polymerization. As shown in Figures 37 and 38, the predictions agree extremely well with the experimental data for various volume fractions of fillers.

ACKNOWLEDGMENTS

I wish to acknowledge my managers and colleagues at Eastman Kodak Company who have encouraged and supported my work on the mechanics of polymers. These include especially Dr John Pochan, Dr Allen Caton, Mr William Hunt, Mr Richard Gammons, Dr Glenn Pearson, Mr David R Smith, Mr Charles Hura, and Dr Yeh-Hung Lai. Dr Pochan has read through the article and has given many insightful comments. Finally, and most importantly, particular appreciation is due to my family, especially my wife, Ying, for her inspiration, encouragement and support.

Molecular spectroscopy as provided using the near-infrared (NIR) measurement technique is valuable for polymer identification, characterization, and quantitation. NIR spectroscopy can be completed for in situ process applications where no sample preparation is required, and where rugged optical systems are a necessity. The NIR region is a complimentary band of the electromagnetic spectrum to the mid-infrared (MIR) region (4000–500 cm^{-1}), encompassing 13 333–4000 cm^{-1} or 750–2500 nm (nanometers, 10^{-9} m).

NIR and infrared (IR) spectroscopy are routinely used to qualify monomers prior to polymerization reactions. NIR is used to measure the kinetics of polymer onset and can be used to detect end-point completion and initiator compound levels in polymerization reactions. NIR spectroscopy can also be used to sort polymers and to control the quality of incoming raw monomers and finished polymeric materials. Molecular spectroscopy using the NIR and IR measurement techniques is often used for competitive analysis and to determine thermal or photoinduced oxidation or degradation reactions in polymers. This article delineates the background, theory, band assignments, and applications of NIR spectroscopy for the measurement of polymers and rubbers.

1 INTRODUCTION

H. Staudinger[1] was one of the first investigators into macromolecular compounds. His original work resulted in the synthesis and test method development of numerous macromolecules which we now refer to as polymers, meaning poly (many) + mers (parts). Many chemists disagreed with Staudinger's pioneering work and would not accept the widespread existence of macromolecules held together by covalent bonds. Herman Mark[2,3] provided support for Staudinger's thesis by confirming that cellulose consisted of a number of carbon, hydrogen, and oxygen atoms held together by covalent bonds. This work of Mark's led to the discovery that macromolecules as

Encyclopedia of Analytical Chemistry
R.A. Meyers (Ed.) Copyright © John Wiley & Sons Ltd

polymers do not have specific molecular weights, but rather exhibit a range of molecular weights that are statistically averaged and reported in units termed daltons, where 1 dalton is equivalent to 1 amu (atomic mass unit). Thus, the molecular weights of polymer systems are reported as an average molecular weight in X daltons, with a standard deviation of $\pm Y$ daltons.

Since the discoveries of Herman Mark, polymer science has depended much on the use of instrumentation for confirmation and characterization of molecular weights and structures of polymers, particularly, DSC (differential scanning calorimetry), TGA (thermal gravimetric analysis), proton and carbon-13 NMR (nuclear magnetic resonance) spectrometry, MS (mass spectrometry), LC/MS (liquid chromatography/mass spectrometry), X-ray diffraction, GPC (gel permeation chromatography), and GC (gas chromatography). Spectroscopic techniques often used in polymer analysis and characterization include hyphenated methods such as GC/IR and TGA/IR, as well as ATR (attenuated total reflectance)/IR, DRIFTS (diffuse reflectance Fourier transform spectroscopy), specular reflectance, transmission IR, and Raman spectroscopy. Each of these analytical measurement techniques is capable of yielding complementary information relative to a macromolecule of interest, such as modern polymer systems.

NIR and IR are routinely used to qualify monomers prior to polymerization reactions. NIR is used to measure the kinetics of polymer onset and can be used to detect end-point completion and initiator compound levels in polymerization reactions. NIR spectroscopy can also be used to sort polymers and to control the quality of incoming raw monomers and finished polymeric materials. Molecular spectroscopy using the NIR and IR measurement techniques is often used for competitive analysis and to determine thermal or photoinduced oxidation or degradation reactions in polymers. In summary, molecular spectroscopy as provided using the NIR measurement technique is valuable for polymer identification, characterization, and quantitation. NIR spectroscopy can be completed for in situ process applications where no sample preparation is required, and where rugged optical systems are a necessity.

Some of the earliest work published was in applying IR and NIR spectroscopy to polymer characterization.[5–14] The NIR region is a complimentary band of the electromagnetic spectrum to the MIR region (4000–500 cm^{-1}). The NIR region is generally defined as 13 333–4000 cm^{-1}, or 5750–2500 nm. The majority of analytical work in the NIR region is reported by the literature in nanometers and so this chapter will follow the same convention. The most notable and earliest NIR work was completed by J.W. Ellis and published in 1928.[4] Ellis' review work reported on absorption studies of organic liquids and cited 44 separate papers published prior to June, 1929. Ellis reported bands for carbon–hydrogen-based organic liquids to be present at 2.3–2.2, 1.7, 1.4, 1.2, 1.0, and 0.9 μm. W. Kaye provided a review of NIR spectroscopic publications from the late 1920s up until April 1954. His work cites 106 references demonstrating the ''hydrogenic'' stretching vibrations for C−H, N−H, and O−H containing molecules from 0.7 to 3.5 μm. The most notable review papers describing the history and use of NIR molecular spectroscopy for organic compound and polymer characterization are found in work by Kaye,[5] Goddu,[6] Whetsel,[7] and Stark et al.[8] Excellent references are directly related to polymer analysis using IR and NIR spectroscopy.[9–14]

IR energy is the electromagnetic energy of molecular vibration. The energy band is defined for convenience as the NIR (0.75–2.50 μm); the IR 2.50–40.0 μm; and the far-IR (FIR) (40.0–1000 μm). Table 1 illustrates the region of the EMR (electromagnetic radiation) spectrum referred to as the NIR region. The table shows the molecular interactions associated with the energy frequencies (or corresponding wavelengths) of the various regions. Dominant NIR spectral features include methyl C−H, methylene C−H, methoxy C−H, carbonyl C−H, aromatic C−H, hydroxyl O−H; N−H from primary amides, secondary amides (both alkyl, and aryl group associations), N−H from primary, secondary, and tertiary amines; and N−H from amine salts.

Light has both particle and wave properties; quantum theory tells us that the energy of a light ''particle'' or photon (E_p) is given by Equation (1)

$$E_p = h\nu \tag{1}$$

where h is Planck's constant (or 6.6256×10^{-27} erg-s) and ν is the frequency of light (or the number of vibrations per second in units of s^{-1}). Thus the energy for any specific photon can be quantified, and it is this energy which interacts with the vibrating bonds within *IR active molecules*.

In this text the wavelength from 350 to 3000 nm (28 500–3333 wavenumbers) will be addressed. First, a

Table 1 Spectroscopic regions of interest for polymer analysis

Region	Wavelength (nm)	Characteristic measured
Visible	360–780	Electronic transitions: color measurements
NIR	780–2500	Overtone and combination bands of fundamental molecular vibrations
IR	2500–40 000	Fundamental molecular vibrations: stretching, bending, wagging, scissoring

review of the relationships between micrometers, centimeters, and nanometers to wavenumbers and frequency is given using Equations (2–5):

$$\bar{\nu} = \frac{\nu}{(c/n)} \tag{2}$$

$$\bar{\nu} = \frac{1}{\lambda} \tag{3}$$

and

$$\nu = \frac{(c/n)}{\lambda} \tag{4}$$

$$\lambda = \frac{(c/n)}{\nu} \tag{5}$$

where $\bar{\nu}$ is the wavenumber (number of waves per unit length), ν is the frequency (number of vibrations per unit time), c is the velocity of light in a vacuum (approximately 2.998×10^{10} cm s^{-1}), n is the refractive index of material in which c is measured (air is 1.0003) and λ is the wavelength (length of one complete wave); note that λ in nanometers $= 10^7/\bar{\nu}$.

Each of the above symbols is in the following units:

- $\bar{\nu}$ in cm^{-1} *or* 1/cm
- ν in s^{-1} *or* 1/s *or* hertz (Hz)
- λ in cm.

Light from a NIR spectrophotometer is directed to strike a polymer or rubber matrix consisting of one or more types of macromolecule. If the molecules do not interact with the light then the light passes through the matrix unaffected. If molecules interact with the light in a very specific way (i.e. molecular absorption) we refer to them as *active* or *IR active*. For NIR energy, the overtones of X–H bonds, that is N–H, C–H, and O–H, stretching and bending are of the greatest interest. IR active molecules can be seen as consisting of mechanical models with vibrating dipoles. Each dipole model vibrates with a *specific frequency* and *amplitude* as shown in the simple model in Figure 1.

Note that the term *frequency* refers to the number of vibrations per unit of time, designated by the Greek letter ν (nu) and generally specified in units of s^{-1} or hertz. *Amplitude* is defined by the interatomic distance covered at the extremes of the vibrating dipole, and is dependent upon the amount of energy absorbed by the IR active bond. When incoming photons from a spectrophotometer source lamp (after they have passed through the monochromator or interferometer) strike different molecules in a sample, two direct results

Figure 1 Model of IR active molecule as a vibrating dipole between two atoms.

may occur: (1) the disturbing energy does not match the natural vibrational frequency of the molecule; or (2) the disturbing frequency does match the vibrational frequency of the molecule. When there is a match between the disturbing frequency of the illumination energy and the natural vibrational frequency of a molecule in the sample, the molecule absorbs this energy, which in turn increases the vibrational amplitude of the absorbing dipoles. However, regardless of the increase in amplitude, the frequency of the absorbing vibration remains constant.

Another name for the dipole model from Figure 1 is an *ideal harmonic oscillator* (HO). The frequency at which the dipole (or ideal HO) vibrates (stretches or bends) is dependent upon the bond strength and the masses of the atoms bonded together. When the HO vibrates, the vibrational energy is continuously changing from kinetic to potential and back again. The total energy in the bond is proportional to the frequency of the vibration. The use of Hooke's law (in our case referring to the elasticity properties of the HO), is applied to illustrate the properties of the two atoms with a well-behaved spring-like bond between them. The natural frequency of vibration for a bond (or any two masses connected by a spring) is given by the well-known relationship, Equation (6)

$$\nu = \frac{1}{2\pi} \sqrt{\frac{K}{\left(\frac{1}{m_1} + \frac{1}{m_2}\right.}} \tag{6}$$

where K is a force constant that varies from one bond to another; m_1 is the mass of atom 1 and m_2 is the mass of atom 2. Note that as a first approximation the force constant (K) for single bonds is one-half times that of a double bond, and one-third that of a triple bond. Also note that as the mass of the atoms increases, the frequency of the vibration decreases.

The effects of quantum mechanics on a simple HO indicate that we cannot treat the bond between two atoms quite as simply as two masses connected by a spring. This is no surprise since quantum mechanical evidence has shown that vibrational energy between atoms in a molecule is quantized into discrete energy levels. When the conditions are right, vibrational energy in a molecule "jumps" from one energy level to another. The discrete vibrational energy levels for any molecule (E_{VIB}) are given by Equation (7)

$$E_{\mathrm{VIB}} = h\nu \left(\upsilon + \frac{1}{2}\right. \tag{7}$$

where h is Plank's constant, ν is the vibrational frequency of the bond and υ (represented by the Greek upsilon) is

the quantum number (which can only have the integer values of 0, 1, 2, 3, and so on).

The concept of an *anharmonic oscillator* allows for the more realistic calculations of the positions of the allowed overtone transitions. The energy levels for these overtones are not found as the product of exact integer multiples times the fundamental frequency. In fact, the following expression defines the relationships between wavenumber (for a given bond) and the vibrational energy of that bond. The relationship is calculated from the Schrödinger equation to yield Equation (8)

$$\bar{\nu} = \frac{E_{\text{VIB}}}{hc} = \bar{\nu}_1 \upsilon - x_1 \bar{\nu}_1 (\upsilon + \upsilon^2) \tag{8}$$

where υ is an integer number, that is, 0, 1, 2, 3, . . ., n and $x_1\bar{\nu}_1$ is the unique anharmonicity constant for each bond.

Calculations of band positions using Equation (8) will more closely approximate observed band positions than those calculated from the ideal HO expression found in Equation (6). As a rule of thumb, the first overtone for a fundamental can be calculated as a 1–5% shift due to anharmonicity, thus the expression, Equation (9)

$$\lambda = \frac{\lambda_1}{\kappa} + \frac{\lambda_1}{\kappa}(0.01, 0.02, \ldots, 0.05) \tag{9}$$

is used to illustrate the occurrence of overtones absorption using a fundamental absorption occurring at approximately $2632\,\text{cm}^{-1}$; converting to nanometers using $10^7/\nu(\text{in cm}^{-1}) = 3800\,\text{nm}$; the first overtone would occur at, Equation (10)

$$\nu = \frac{3800}{2} + (3800 \times 0.01) = 1938\,\text{nm} \quad \text{to}$$
$$\nu = \frac{3800}{2} + (3800 \times 0.05) = 2090\,\text{nm} \tag{10}$$

and thus one would expect the first overtone to occur somewhere between 1938 and 2090 nm rather than the 1900 nm calculated using a simple HO model.

Molecules that absorb NIR energy vibrate in two fundamental modes, *stretching* and *bending*. Stretching is defined as a continuous change in the interatomic distance along the axis between two atoms, and bending is defined as a change in the bond angle between two atoms. Figure 2 illustrates the often repeated stretching and bending interactions defining IR active species within IR active molecules. Note that NIR spectral features arise from the molecular absorptions of the overtones and combination bands from fundamental vibrational bands found in the MIR region. For fundamental vibrations there exists a series of overtones with decreasing intensity as

Figure 2 Illustration of aliphatic C–H (as predominantly methyl C–H str.) from 2,2,4-dimethyl pentane (iso-octane). (a) The fourth overtone (5ν) with combination bands, (b) the third overtone (4ν) with combination bands, (c) the second overtone (3ν) and combination bands, (d) the first overtone (2ν) and combination bands and a portion of the fundamental band.

the transition number (overtone) increases. Combination bands arise as the summation of fundamental bands, their intensity decreasing with an increase in the summation frequency.

Fundamental and overtone absorptions arise when molecules are excited from the ground state to higher energy excited states. Fundamental vibrations will change in amplitude when absorbing energy of the same frequency from an outside source that strikes the vibrating bond(s). Variations in hydrogen bonding manifest themselves as changes in the force constants of the X−H bonds. Generally bands will shift in frequency and broaden due to the formation of hydrogen bonding. Since combination bands result as the summation of two or more fundamental vibrations, and overtones occur as the result of the multiples of fundamental vibrations, frequency shifts related to hydrogen bonding have a greater relative effect on combination and overtone bands than on their corresponding fundamentals. This feature of the NIR region alerts one to the importance of the relative hydrogen bonding effects brought about by solvent and temperature variations.

Precise band assignments are difficult in the NIR region because a single band may be attributable to several possible combinations of overlapping overtone and combination bands. The influence of hydrogen bonding results in band shifts to lower frequencies (higher wavelengths); a decrease in hydrogen bonding due to dilution and higher temperatures results in band shifts to higher frequencies (lower wavelengths). Band shifts of the magnitude of 10–100 cm^{-1}, corresponding to from a few nanometers to 50 nm may be observed. The substantial effect of hydrogen bonding should be kept in the forefront of thought when composing calibration sample sets and experimental designs for NIR experiments.

NIR spectra contain information relating to differences in bond strengths, chemical species, electronegativity, and hydrogen bonding. For solid samples, information with respect to scattering, diffuse reflectance (DR), specular reflectance, surface gloss, refractive index, and polarization of reflected light are all superimposed on the NIR vibrational information. Aspects related to hydrogen bonding and hydronium ion concentration are included within the spectra. Light can interact with the sample as reflection, refraction, absorption, scattering, diffraction, and transmission. Signal losses from the sample can occur as specular reflection, internal scattering, refraction, complete absorption, transmission loss during reflectance measurements, and trapping losses. Spectral artifacts can also arise as offset or multiplicative errors caused by coloration of the sample, variable particle sizes and resultant variability in apparent pathlength, refractive index changes in clear liquids relative to temperature changes, and pathlength differences due to temperature-induced density changes.

The types of vibration found in NIR and IR spectroscopy are designated by ν (Greek letter nu) with a subscript designating whether the vibration is stretching (s) or bending (b), for example, stretching is designated as $\tilde{\nu}_s$, and bending vibrations as $\tilde{\nu}_b$. Combination bands resulting from the sum of stretching and bending modes are designated as $\tilde{\nu}_b + \tilde{\nu}_s$ and harmonics are designated as $k\tilde{\nu}_s$, where k is an integer number as 2 (first overtone), 3 (second overtone), ..., k ($k-1$th overtone), and $\tilde{\nu}_s$ is the frequency of the fundamental stretch vibration for a specific functionality.

As an exercise, apply this brief lesson in quantum mechanics to a problem using *n*-decane. Typical NIR spectra of *n*-decane, $CH_3(CH_2)_8CH_3$, appear in Figure 3. *n*-Decane, a member of a class of hydrocarbon compounds known as paraffins (alkanes), contains two methyl groups and eight methylene groups. Thus we would expect to see strong methylene C−H stretch absorptions as well as notable methyl C−H stretch absorptivity. Indeed, the spectrum of decane shows combination bands for methyl and methylene C−H stretch plus C−H bend as well as overtone bands. To calculate the expected positions for methyl C−H bands we relate the following calculations, assuming an ideal HO model.

Methyl C−H combination bands appear near the sum of two or three fundamental bands. For example (in the case of *n*-decane), a C−H methyl combination band should occur near 2262.4 nm. To illustrate, 2960 cm^{-1} (C−H stretch) + 1460 cm^{-1} (C−H bend) = 4420 cm^{-1}; converting to wavelength we calculate $(10^7/4420\,cm^{-1}) = 2262.4$ nm.

As previously noted, overtones (also termed harmonics) occur at integer multiples of fundamental bands. For example, using the simple HO model, C−H stretch overtones should occur at 1689 nm, 1126 nm, and 845 nm. For the example of *n*-decane we note the following:

- first overtone at 2960 cm^{-1}(C−H stretch) × 2 = 5920 cm^{-1} = 1689 nm;
- second overtone at 2960 cm^{-1}(C−H stretch) × 3 = 8880 cm^{-1} = 1126 nm;
- third overtone at 2960 cm^{-1}(C−H stretch) × 4 = 11 840 cm^{-1} = 845 nm.

When laboratory measurements are taken for *n*-decane it can be noted that band positions do not match the calculations for ideal. In fact, the actual positions are approximately 2310 nm, 1725 nm, 1212 nm, and 930 nm, respectively. As noted, an application of the anharmonic oscillator expression (Equations 8 and 9) allows better approximations of actual band positions. In fact using a

Figure 3 Illustration of aliphatic C−H (as predominantly methylene C−H str.) from *n*-decane. (a) The fourth overtone (5ν) with combination band, (b) the third overtone (4ν) with combination bands, (c) the second overtone (3ν) and combination bands, (d) the first overtone (2ν) and combination bands and a portion of the fundamental.

2.0% anharmonicity yields theoretical band positions as 2308 nm, 1723 nm, 1149 nm, and 862 nm (slightly closer to actual than the simple HO calculations).

The energy absorbed by a matrix consisting of polymeric compounds depends upon the chemical composition of the matrix, defined by the species (or types) of molecules present, the concentration of these individual species, and the interactions between the molecules in the matrix. In order for NIR (or any other vibrational spectroscopic measurement technique) to be valid one must be absolutely assured that different types of molecule absorb at unique frequencies. Owing to the broad-band nature of NIR spectra, consisting of overlapping combination and overtone bands, the individual species are not well resolved as they are in the MIR region. In addition, many compounds absorb NIR energy throughout the entire wavelength region making it difficult, if not impossible, to resolve a usable baseline clearly for simple peak height or peak area quantitative methods. This brings one to the same conclusion drawn by early investigators that the NIR region is not especially useful as a quantitative measurement technique. At the very least, novel techniques for spectral manipulation were required to interpret the poorly resolved bands and compensate for background interferences. The first assumption in spectroscopic measurements is that Beer's law relationship applies between a change in spectrometer response and the concentration of analyte material present in a sample specimen. The Bouguer, Lambert, and Beer relationship assumes that the transmission of a sample within an incident beam is equivalent to 10 exponent the negative product of the molar extinction coefficient (in mol^{-1} cm^{-1}), times the concentration of a molecule in solution (in mol^{-1}) times the pathlength (in cm) of the sample in solution. There are some obvious (and not so obvious) problems with this assumption. The main difficulty in the assumed relationship is that the molecules often interact, and the extinction coefficient may vary due to changes in the molecular configuration of the sample. The obvious temperature, pressure, and interference issues also create a less than ideal situation for the analyst. However, for many (if not most) analytical problems the relationship holds well enough.

Properties of the Bouguer, Lambert and Beer (Beer's law) relationship, Equation (11):

$$T = \frac{I}{I_0} = 10^{-\varepsilon cl} \tag{11}$$

where T is the transmittance (T), I_0 is intensity of incident energy, I is the intensity of transmitted light, ε is the molar extinction coefficient (in L mol^{-1} cm^{-1}), C is the concentration (in mol^{-1}), and l is the pathlength (in cm).

To simplify Equation (11) into its more standard form showing absorbance as a logarithmic term used to linearize the relationship between spectrophotometer response and concentration, gives the expression, Equation (12), as the relationship between absorbance (A) and concentration

$$A = -\log\left(\frac{I}{I_0}\right) = -\log(T) = \varepsilon cl \qquad (12)$$

The following statements hold true for what is most often termed Beer's law: (1) the relationship between T and concentration is nonlinear, yet (2) the relationship between absorbance and concentration is linear. Beer's law is the common basis for *quantitative* analysis. Knowledge of Beer's law allows us to calculate the maximum theoretical dynamic range for an instrument using a few simple mathematical relationships. A measured spectrum is the ratio of the sample and reference channels in transmission. As in the case of single beam instruments, in practice the final T spectrum from this device is given as, Equation (13)

$$T = \frac{\text{Sample}_T - \text{Dark}}{\text{Reference}_T - \text{Dark}} \qquad (13)$$

To convert this to an absorbance spectrum is completed using the relationship, Equation (14)

$$A = \log_{10}\left(\frac{1}{T}\right) \qquad (14)$$

2 REVIEW OF NEAR-INFRARED SPECTROSCOPY IN POLYMER AND RUBBER ANALYSIS

Table 2 shows the broad range of applications which are possible using the NIR spectral region. The list of applications which have been successfully implemented using the NIR and SW (short wave)/NIR techniques is vast. The NIR technique offers a possible solution to many other process analytical measurement requirements for polymers and rubbers than those listed in Table 2.

Table 2 Common applications for NIR in polymers

Matrix	Constituents
Copolymers	Vinyl acetate, PVC, PVA
Epoxy resins	Terminal CH_2 group
Ethylene–propylene blends	Percent polymer
Glycols	Water, OH number
Polymers (in general)	Cure kinetics, chemical/physical properties, phase separation, hydroxyl number
Polymer oxidation	Unsaturation and polyene formation due to thermal or photoinduced oxidation
Polymer mixtures	In situ quantitative analysis of individual polymer types
Polyolefins	Antioxidants
Polyols	Hydroxyl number
Polyurethane foams	Physical properties
Poly (ether urethane)	Bulk composition
Poly (ethylene terephthalate)	Crystallinity/morphology
Proteins	Water binding

PVC, polyvinyl chloride; PVA, polyvinyl alcohol.

2.1 Sorting Polymers

Polymer sorting for recycling operations has received attention. This technique provides automatic recognition of polymer type in a recycling operation and demonstrates the powerful capability of molecular spectroscopy for this type of application. A method has been developed for sorting plastics from nonplastics in waste recycling. Partial least squares (PLS) is used for data reduction in the classification of NIR spectral images.[15] A method for the discrimination of plastics from nonplastics in household waste on the basis of images taken in six wavelength ranges between 1100 and 2500 nm has been reported.[16] The use of this technique provided correct classification in 80% or better of the test cases.

Identification of plastics among nonplastics in mixed waste by remote sensing NIR imaging spectroscopy has been described.[17] In this application household waste was characterized by a sequence of images taken in four wavelength regions using NIR imaging spectrometry. Each sample was represented by a three-dimensional stack of NIR images. The method is insensitive to sample size and relative position within the camera cone of focus. The method was useful even with slight sample movement. An improved data processing method for reduction of experimental artifacts in a multivariate stack of remotely sensed NIR images is described.[18] The images provide data for real-time plastic identification and classification. Reference and dark current spectral images were used to correct the raw spectral images for normal fluctuations in background, illumination geometry, lamp source intensity, and optical transmission.

A device for on-line postconsumer package identification using NIR spectroscopy combined with a FuzzyARTMAP classifier has been demonstrated in an industrial environment.[19] A 30-cm wide conveyor belt moving at $1\,\text{m}\,\text{s}^{-1}$ carried the waste through an optical path defined by a 220-V, 500-W halogen lamp and collection optics mounted at one side of the belt and a metal reflector (60 cm from the collection optics) at the other. The collection optics were coupled by an optical fiber to a computerized f/2.8 grating spectrometer with an InGaAs detector. Radiation backscattered from opaque objects on the belt was detected, together with radiation

reflected back through transparent objects; the reflector provided the reference signal when the optical path was not obstructed. Spectra ($158\,s^{-1}$) were recorded in the range 900–1700 nm. Use of a neural-network classifier gave an accuracy of >97% in the classification of objects made of poly(ethylene terephthalate), polystyrene, PVC and cardboard, but was slightly less reliable at distinguishing between polyethylene and polypropylene, owing largely to the frequently composite nature of objects made from these materials.

The direct examination of NIR absorption bands can provide information about the inter- and intramolecular hydrogen bonding and other interactions of polymers, which are not only used to study, for example, the curing of epoxy resins, but can also be used in process control in the production of polymers and their blends.[20]

An optoacoustic FTIR (Fourier transform infrared spectroscopy) gas analyzer was used on-line with a fixed-bed pyrolysis reactor that consisted of a vertical quartz tube (1-cm i.d.) heated by a Lindberg furnace. Each sample (50–100 mg) was divided into portions that were packed in the tube separated from each other by quartz wool. A stream of He ($0.6\,L\,min^{-1}$) entered at the bottom of the tube and exited at the top, passing through a filter before it reached the analyzer. The reactor was also coupled to a gas chromatograph fitted with FID (flame ionization detection) or thermal conductivity detection. The results are tabulated. The major toxic products of polyacrylonitrile were HCN and NH_3; nylons produced NH_3, but only minor amounts of HCN. Both types of polymer produced CO. These by-products were monitored using the commercial device.[21]

Three classifiers, namely, adaptive resonance theory-based artificial neural network (ART-2a), multilayer feedforward backpropagation of error neural networks (MLFBP) and SIMCA (soft independent modeling of class analogies), were compared for sorting postconsumer plastics into classes (poly(ethylene terephthalate), poly(propylene), polyethylene, PVC, polystyrene) using NIR data.[22] The spectra were recorded using an advanced type of fast NIR spectrometer equipped with a InGaAs diode-array multichannel detector. With a minimum integration time of 6.3 ms, 158 complete NIR spectra (825–1700 nm) can be recorded per second. The performance of the classifiers was quantitatively evaluated by a repeated validation procedure based on the method of medium overlap between data clusters. MLFBP exhibited a slightly better discrimination power than ART-2a. Both types of neural network performed significantly better than SIMCA.

2.2 Polymer Reaction Monitoring

A variety of applications referring to the use of NIR for monitoring polymer reactions is available within the literature. Several examples of the current work in this area includes work by Siesler.[23] A review is presented on applications of optical-fiber remote NIR spectrometry, the examples quoted being the monitoring of the consumption of methyl methacrylate during its polymerization, the study of structural changes during the formation of poly(ethylene terephthalate) film, monitoring the reactive extrusion of styrene/maleic anhydride copolymer with 6-aminohexanoic acid at up to 300 bar and up to 400 °C, and the rapid identification of polymer waste.

The severe conditions (temperatures greater than 260 °C with turbulence) that obtained during the manufacture of polyoxyethylene and polyoxypropylene glycols necessitate remote analysis of the samples taken in situ; this can be accomplished by use of a commercial NIR polyol analyzer, which is connected by optical fibers to a stainless-steel immersion-sampling absorption cell (pathlength 6 mm). Thirty-two scans are co-added for each sample and corrected internally for absorption by the fibers. The establishment of calibration equations for hydroxyl number and acid value by multilinear least-squares regression on the basis of laboratory-analyzed samples is described; these gave standard errors of calibration of 0.41 and 0.28, respectively. A result was obtained in 1 min, and showed a relative error of 1.5% with respect to the laboratory value.[24]

On-line remote monitoring of thermoset resin cure using NIR external reflection spectroscopy is described by Xu et al.[25] NIR analysis in polymer reactions is given by Dallin.[26] The challenge of introducing NIR on-line in polyol production is described by Stromberg.[27] In-line process monitoring on polymer melts by NIR spectroscopy is given by Fischer et al.[28] In-line measurement of copolymer composition and melt index is explained by Hansen and Vedula.[29] In situ real-time monitoring of epoxy/amine kinetics by remote NIR spectroscopy is demonstrated by Mijovic et al.[30] A patent describing the process for measurement of the degree of cure and percent resin of glass-fiber-reinforced epoxy resin is given by Moe and Konicek.[31]

3 SAMPLE PREPARATION

A variety of sample presentation methods are available to the analyst. These include transmission (straight and diffuse), reflectance (specular and diffuse), transflectance (reflectance and transmission), and interactance (a combination of reflectance and transmission). In the selection of a pathlength for measurement, the following rules of thumb generally apply: for the ultraviolet (UV) region of 190–350 nm, a pathlength of 1 mm–10 cm is used, noting that 1 cm is most often used for hydrocarbon

Table 3 Sample presentation methods for polymers and rubbers

Sample type	Sample presentation	Comments
Liquids (lower viscosity)	T and DT	Maintain instrument within linear measurement range, that is generally less than 1.5 Au
Slurries (high viscosity)	T and DT	Maintain instrument within linear measurement range, that is generally less than 1.5 Au
Solids and smaller particles	DR	For DR use infinite optical thickness
Webs	DR and DT	For DR use infinite optical thickness
Pellets (large particles)	DR and DT	For DR use infinite optical thickness

Au = absorbance units.

measurements. For the SW/NIR region of 800–1100 nm, pathlengths ranging from 5 to 10 cm are typically used. For longwave (LW) NIR (LW/NIR) of 1100–2500 nm, common pathlengths for hydrocarbons include 0.1–2 cm.

The sample presentation geometries most often used in NIR measurements are given in Table 3. For this table the abbreviations used designate transmittance (T), diffuse transmittance (DT), and diffuse reflectance (DR). T and DT have identical sample presentation geometry, but the sample for DT is a series of particles allowing light to penetrate without significant backscatter. DR is used for samples of infinite optical thickness that will not transmit light if T or DT is used. The ideal surface for DR is a Lambertian or isotropic surface where light is reflected diffusely or evenly throughout a hemisphere above the surface.

Samples exhibit different optical characteristics which must be considered for optimum spectroscopic measurement. Standard clear samples or solutions are measured using transmission spectroscopy. Highly colored samples are generally measured using transmission spectroscopy unless the optical density exceeds the linear range of the measuring instrument. At this point either dilution or reducing the pathlength is desirable.

Fine scattering particulates of 5 to 25 times the measuring wavelength are measured using DT or DR methods. The scattering produced by some of the reflected light creates a pseudopathlength effect. This effect is compensated for by using scatter correction data processing methods for quantitative measurements.

Large scattering particulates that are in the order of 100 times the measuring wavelength in diameter present a challenge for measurements as the particles intercept the optical path at random intervals. Signal averaging can be employed to compensate for random signal fluctuations. Reflectance spectroscopy can be used to measure the size, velocity, and concentration of scattering particulates within a flowing stream.

Very high absorptivity (optically dense) materials with absorbances above 4–6 Au (absorbance units) are difficult to measure accurately without the use of double monochromator instruments which have stray light specifications below 0.0001% T. Measurements can be made with extremely slow scanning speeds and by opening the slits during measurement. These measurements should be avoided by the novice unless high-performance instrumentation and technical support are available.

4 INTERPRETIVE SPECTROSCOPY OF ORGANIC COMPOUND SPECTRA FOR POLYMERS AND RUBBERS IN THE NEAR-INFRARED REGION

Several tables and charts within this chapter describe the approximate band positions for organic compound spectra. Polymers and rubbers exhibit these band positions which will vary depending upon the molecular structure and the associated or attached chemical groups. Table 4 demonstrates the positions of major chemical groups encountered in analysis of polymer and rubber materials. The accompanying text describes the individual molecular vibrations and band assignments in much greater detail.

4.1 Aliphatic Hydrocarbons (*n*-Alkanes) including Polymeric Forms

The number of normal vibrations occurring within the IR region for saturated hydrocarbons equals $3N - 6$, where N is the sum of carbon plus hydrogen atoms, for example, *n*-hexane (C_6H_{14}) exhibits $3(20) - 6 = 54$ normal vibrational modes. Internal rotation and overlapping of bands complicate the interpretation of alkane (paraffinic) group spectra. C–H stretching vibrations can be expressed to a first approximation by the straightforward use of Hooke's law describing the vibration between two masses connected by a vibrating spring as previously presented.

The first consideration in the description of alkane group spectral interpretation would include the C–H stretching vibrations for methyl ($-CH_3$) and methylene ($-CH_2-$) groups. The methyl C–H stretching vibrations are found in two basic modes: the asymmetric (degenerate or out-of-phase) methyl C–H stretch near 3377 nm, and the symmetric (in-phase) methyl C–H stretch near 3482 nm. Three C–H stretching modes are observed

Table 4 C–H, N–H, and O–H stretch absorption bands for specific LW/NIR (1100–2500 nm) functional groups (first to fourth overtones)[32]

Structure	Bond vibration	Location (in nm) of first overtone	Location (in nm) of second overtone	Location (in nm) of third overtone	Location (in nm) of fourth overtone
ArCH (Aromatics)	C–H stretching	1680–1684	1143	875	715
. CH_2–CH_2. (Methylene)	C–H stretching	1726–1727	1212	927–930	761–764
. CH_3 (Methyl)	C–H stretching	1743–1762	1191–1194	911–915	745–748
. CH_3 (Methyl)	C–H combination	2020–2050	1347–1367	–	–
>C=O (Carbonyl)	>C=O stretching	2915	1920–1945	1420–1460	1140–1170
R–OH (Alcohols)	O–H stretching	1410–1455	940–970	–	–
ArOH (Phenols)	O–H stretching	1421–1470	940–980	–	–
HOH (Water)	O–H stretching	1440–1485	960	–	–
Starch	O–H stretching	1451	967	–	–
Urea	Sym. N–H stretching	1460	973–993	–	–
. $CONH_2$ (Primary amides)	N–H stretching	1463–1484	975–989	–	–
. CONHR (Secondary amides)	N–H stretching	1472	981	–	–
Cellulose	O–H stretching	1490	993	–	–
$ArNH_2$ (Aromatic amines)	N–H stretching	1493	995	–	–
. NH (Amines, general)	N–H stretching	1500	1000	–	–
Protein	N–H stretching	1511	1007	–	–

corresponding to three coupled C–H stretching vibration oscillators. Note that the absorption coefficient for methyl C–H stretch remains constant irrespective of increasing alkane chain length. The methylene C–H stretching vibrations are also found in two basic modes: the asymmetric (degenerate or out-of-phase) methylene C–H stretch near 3418 nm, and the symmetric (in-phase) methylene C–H stretch near 3505 nm.

Figure 2 illustrates the repetitive aliphatic (as predominantly methyl C–H stretching) information present within the NIR region for the fourth through first overtone spectra of isooctane. The repetitive molecular vibrational information within the spectra allow selection of the optimal pathlength for transmission work in the NIR spectral region. The fourth and third overtone measurements are taken using a 10.0-cm pathlength cell. The second and first overtone measurements were taken using 2.0-cm and 1.0-mm pathlength cells, respectively.

Figure 3 illustrates the repetitive aliphatic (as predominantly methylene C–H stretching) information present within the NIR region for the fourth through first overtone spectrum of *n*-decane. The repetitive molecular vibrational information within the spectra allow selection of the optimal pathlength for transmission work in these spectral regions. The fourth and third overtone measurements are taken using a 10.0-cm pathlength cell. The second and first overtone measurements were taken using 2.0-cm and 1.0-mm pathlength cells, respectively.

The two methylene stretching modes result from two coupled C–H stretching vibration oscillators. Increasing the chain length within alkane groups brings about a linear increase in the molecular absorption of methylene C–H stretching bands.

The carbon–hydrogen vibrational modes for alkanes also contain both methyl and methylene bending vibrations. The methyl C–H bending vibrations are found in two modes: the asymmetric (degenerate or out-of-phase deformation) methyl C–H bending near 6850 nm, and the symmetric (in-phase) methyl C–H bending near 7273 nm. This functional group vibrational frequency is dependent upon the atom to which the methyl group is attached. There is no coupling of methyl C–H bending modes to the rest of the system.

The methylene C–H bending vibrations are found in four basic modes: the symmetric (scissoring) methylene C–H bending with no coupling near 6873 nm, and the in-phase twisting vibration, where coupling is observed, near 7693 nm. The in-phase rocking vibration for alkanes with four or more carbons is not found within the NIR region. In addition other bending modes of methyl and methylene can be observed. The alkane carbon-to-carbon stretching, and carbon-to-carbon bending vibrations also occur as weak group frequencies.

4.2 Alkenes (Olefins) and Alkynes (Acetylenes)

The olefins include bands for saturated hydrocarbons as well as the olefinic C=C stretching and olefinic C–H stretching and bending vibrations.

4.3 Olefinic C–H Stretch

Fundamental olefinic C–H stretch occurs near 3280 nm. C–H stretch for an unsaturated carbon occurs below 3333 nm. The saturated carbon C–H bond stretching fundamental occurs above 3333 nm. Olefinic C–H stretch

can occur as an end group, for example R−R−C=C; or as an embedded group associated with other carbons on either end, for example, R−C=C−R. The absorption bands for these two olefinic types occur for the end group-type from 3226 to 3268 nm. Note that compounds containing the vinyl group ($-CH=CH_2$) have weak absorption bands near 3273 nm.

4.4 Alkyne C−H Stretch

The sp-type C−H stretch for C−H occurs at approximately 3030 nm. The sp^1-type C−H stretch associated with aromatic and olefinic carbons occurs near 3280 nm. The sp^1-type stretch for saturated carbons is observed at the high frequency ranges between 3344 and 3571 nm.

4.5 Olefinic C−H Bend

Two modes of bending occur in olefinic hydrogens, in-plane and out-of-plane. These bands do not appear with any importance within the NIR region and the following two paragraphs are for information only. In-plane bend represents a change in the C−H bond angle along the same plane, occurring near 6920–8333 nm as a weak and not very useful group frequency for the presence of olefinic hydrogens. Out-of-plane bending occurs as the C−H bonds vibrate outside the flat olefinic group plane. Out-of-plane bending occurs at approximately 10 000–15 385 nm and presents excellent IR bands for identifying the presence of olefinic groups; however the overtones do not occur within the NIR spectral region. The out-of-plane C−H bend related bands are group frequencies which are distinct, not being affected by conjugation or coupling with other vibrations in the olefinic molecule.

There is only one IR active C−H bend of the four possible modes for olefinic bending vibrations. The four bending modes include *twisting* or *rotational motion*; opposite twisting at the individual olefinic carbons producing a *torsion* at the C=C bond; wagging, or a motion of the hydrogen bonds; and two forms of wag, one where the two groups of two each hydrogens move in opposite planes causing a rotational motion around a common center of axis and the second wag where all four hydrogens move in or out of the plane together. The first type of wag is Raman only active and the second type of wag is the only IR active type, though not observed in the NIR region.

4.6 Aromatic Systems

Aromatic systems produce strong and sharp IR bands owing to the relatively rigid molecular structures (see Figure 4). There are multiple vibrational modes present

Figure 4 Aromatic C−H stretching as illustrated using toluene NIR spectra. (a) The fourth overtone (5ν) with combination bands, (b) the third overtone (4ν) with combination bands, (c) the second overtone (3ν) with combination bands, (d) the first overtone (2ν) and combination bands and a portion of the fundamental vibrational band.

in aromatic systems including carbon–hydrogen stretching, in-plane bending, and out-of-plane bending. Carbon–carbon interactions include ring stretching and ring bending modes. Internal vibrations caused by groups associated with the aromatic system also exhibit vibrational group frequencies. The total vibrational modes for aromatic systems is equal to $3N - 6$ vibrations, where N is the number of carbons in the ring structure. Carbon–hydrogen stretching vibrations occur from approximately 3226 to 3333 nm. IR spectra of aromatics using high-resolution instrumentation show a pair of composite bands near 3257 nm. These composite bands arise as the combined interactions of several stretching modes.

The carbon–carbon ring stretching occurs as a vibrational pair near 6250 nm. This pair of frequencies is termed a degenerate pair and results from two stretching modes of the carbon–carbon ring stretching. However owing to Fermi resonance, one of the vibrations (near 6270 nm) is not observed in the IR spectrum. When there is substitution on the aromatic ring, the degeneracy is lost and the pair of bands occur near 6250 nm. The 6329-nm band will be more intense if there is conjugation with the aromatic system by an electron withdrawing group, or if substitution by O or N has occurred. Note that the occurrence of overtones for this band are observed near 3228–3481 nm (first overtone), 2173–2426 nm (second overtone), and 1645–1899 nm (third overtone). Paradisubstitution of a benzene ring by two identical groups yields to the center of symmetry rule, and thus the carbon-to-carbon ring stretching is IR forbidden. It follows that if the paradisubstituted groups are not identical, some weak bands will occur near the 6250-nm region.

Figure 4 illustrates the repetitive aromatic (as predominantly aromatic C–H stretching with some slight methyl C–H stretching) information present within the NIR region for the fourth through first overtone spectrum of toluene. The repetitive molecular vibrational information within the spectra allow selection of the optimal pathlength for transmission work in these spectral regions. The fourth and third overtone measurements are taken using a 10.0-cm pathlength cell. The second and first overtone measurements were taken using 2.0-cm and 1.0-mm pathlength cells, respectively.

4.7 Carbonyl Compounds (>C=O)

Compounds containing carbonyl groups exhibit frequencies over a broad range from 5128 to 6452 nm (1950–1550 cm^{-1}), although most often carbonyl associated groups occur near 5831 nm (1715 cm^{-1}). Overtone associated bands for carbonyl compounds occur near 2916 nm (first overtone), 1944 nm (second overtone), and 1458 nm (third overtone). The position or frequency of the carbonyl C=O stretching vibration is affected by the isotope effects and mass change of substituted groups, bond angles of substituted groups, electronic (resonance and inductive) effects, and interactions of these effects. Substituents with higher mass decrease the C=O stretch frequency; increasing the mass or bond angles of substituents also decreases the frequency by up to 40 cm^{-1} at 1715 cm^{-1}; this is equivalent to an increase of 139 nm at 5831 nm. Similarly decreasing the substituent mass, or bond angles between the carbonyl carbon and its substituents increases the frequency by 25 cm^{-1} above the nominal 1715 cm^{-1} carbonyl C=O stretch frequency, equivalent to a decrease in wavelength of 84 nm at 5831 nm. More electronegative (electron withdrawing) substituents will increase the carbonyl carbon–oxygen stretch frequency by up to 100 cm^{-1} above the 1715 cm^{-1} nominal frequency: a decrease of 321 nm at 5831 nm. Conjugation of the carbonyl group to aromatic or olefinic groups tends to lower the frequency for both C=O and C=C by 30–40 cm^{-1} depending on the ring size of the substituent. Electronic effects such as resonance and inductive type produce a double-bond character and increase the frequency of the carbonyl stretch.

4.8 Amides (R–C=ONH–X)

Amides are a special case of carbonyl compounds which are subject to frequency shifts due to hydrogen bonding. The frequencies for dilute solutions of amides can vary by as much as 250–275 nm (75 cm^{-1}) at ~5880 nm compared with the same molecule with hydrogen bonding (such as a Nujol mull preparation). Dilute solutions of amides exhibit carbonyl frequencies as follows. Primary amides ($R–C=O–NH_2$) occur at 5764 nm (fundamental at 1735 cm^{-1}), 3054 nm (first overtone), 2094 nm (second overtone), 1498.6–1729.2 nm (third overtone). Secondary amides (R–C=O–NHR) occur at 5865 nm (fundamental at 1705 cm^{-1}), 2991.2–3225.8 nm (first overtone), 2013.7–2248.3 nm (second overtone), 1524.9–1759.5 nm (third overtone). Tertiary amides, $R–(C=O)–NR_2$, bands are found at 6042 nm (fundamental at 1655 cm^{-1}), 3081.4–3323.1 nm (first overtone), 2074.4–2316.1 nm (second overtone), and 1570.9–1812.6 nm (third overtone).

These respective hydrogen-bonded vibrations occur at shifted frequencies from those above. For primary amides vibration occurs at 5882–6061 nm (fundamental at 1700–1650 cm^{-1}), 2999.8–3333.6 nm (first overtone), 2019.5–2323.4 nm (second overtone), and 1529.3–1818.3 nm (third overtone). For secondary amides vibrations occur at 5952–6116 nm (1680–1635 cm^{-1}), 3035.5–3363.8 nm (first overtone), 2043.5–2344.5 nm (second overtone), and 1547.5–1834.8 nm (third overtone). For tertiary amides, vibrations occur at 6024 nm

(1660 cm^{-1}), 3072.2–3313.2 nm (first overtone), 2068.2–2309.2 nm (second overtone), and 1566.2–1807.2 nm (third overtone). The N–H stretch for amides occurs as two bands between 2976 and 3150 nm (3360 and 3175 cm^{-1}). Geometrically, two forms of amide exist as either the *trans* or *cis* forms. The *trans* form demonstrates a frequency of 3008–3053 nm (3325–3275 cm^{-1}), 1534.1–1679.2 nm (first overtone), 1032.7–1170.3 nm (second overtone), and 782.1–915.9 nm (third overtone). The *cis* form demonstrates a frequency of 3140–3190 nm (3185–3135 cm^{-1}), 1601.4–1754.5 nm (first overtone), 1078.1–1222.8 nm (second overtone), and 816.4–957.0 nm (third overtone). The geometries included are as R–(C=O)–(N–R′)–H where the R and R′ are either in the *trans* or *cis* configuration. The term "amide I" band refers to the C=O carbonyl stretch and the nominal C=O stretch frequency is 5831 nm (1715 cm^{-1}), 2973.8–3207.1 nm (first overtone), 2002.0–2235.2 (second overtone), and 1516.1–1749.3 nm (third overtone). The amide form of the carbonyl has an electronegative N atom, lowered by resonance with the nitrogen electrons and lowered by hydrogen bonding. The C=O nominal frequency for the amide I stretch is approximately 6061 nm (1650 cm^{-1}), 3091.1–3333.6 nm (first overtone), 2080.9–2323.4 nm (second overtone), and 1575.9–1818.3 nm (third overtone).

The term "amide II" refers to the NH_2 scissoring associated with primary amides, R–(C=O)–NH_2. The amide II frequency results from the combined interactions of the C–N stretch and the N–H in-plane bend; these vibrations interact to form bands in the 6494 nm (1540 cm^{-1}) region with overtones at 3311.9–3571.7 nm (first overtone), 2229.6–2489.4 nm (second overtone), and 1688.4–1948.2 nm (third overtone). In addition bands are formed in the 7634–8197 nm (1310–1220 cm^{-1}) region with overtones at 3893.3–4508.4 nm (first overtone), 2621.0–3142.2 nm (second overtone), and 1984.8–2459.1 nm (third overtone). A band at 6410–6515 nm (1560–1535 cm^{-1}) indicates a *trans* substituted amide; this band is lost in the *cis*-amide configuration. Overtones for this band occur at 3269.1–3583.3 nm (first overtone), 2200.8–2497.4 nm (second overtone), and 1666.6–1954.5 nm (third overtone).

4.9 Hydrogen Bonding (X–H···Y)

A hydrogen-bonded molecular system has four possible modes: O–H stretch found at 2941–4000 nm (3400–2500 cm^{-1}) with overtones occurring at 1499.9–2200 nm (first overtone), 1009.7–1533.3 (second overtone), and 764.7–1200 nm (third overtone). R–O–H in-plane bend at 7143–7692 nm (1400–1300 cm^{-1}) with overtones occurring at 3642.9–4230.6 nm (first overtone), 2452.4–2948.6 nm (second overtone), and 1857.2–2307.6 nm (third overtone). The R–O–H out-of-plane bend at 15 152 nm (660 cm^{-1}); no vibrations are found in the NIR region. The –O–H···O stretch is at 57 143 nm (175 cm^{-1}); no vibrations are found within the NIR region.

Specific frequencies for molecules containing O–H with hydrogen bonding include alcohols (R–O–H) with n(O–H) = 2981 nm (3355 cm^{-1}) with overtones at 1520.3–1639.6 nm (first overtone), 1023.5–1142.7 nm (second overtone), and 775.1–894.3 nm (third overtone); carboxylic acids (–COOH) with n(O–H) = 3333 nm (3000 cm^{-1}) with overtones at 1699.8–1833.2 nm (first overtone), 1144.3–1277.7 nm (second overtone), and 866.6–999.9 nm (third overtone); amines (R–NH–X) with n(N–H) = 3000 nm (3300 cm^{-1}), with overtones occurring at 1530–1650 nm (first overtone), 1030–1150 nm (second overtone), and 780–900 nm (third overtone).

In general hydrogen bonding has several main effects on frequency of X–H bands: (1) it lowers the frequency of the X–H stretch compared with the gas phase and dilute liquid phase of a molecule; (2) it raises the X–H bend frequency; (3) it broadens all O–H stretch bands by up to 300–475 nm (300–500 cm^{-1}); (4) it intensifies all bending and stretching X–H bands.

4.10 The O–H Stretch

It is commonly accepted among IR spectroscopists that any fundamental band occurring above 2857 nm (3500 cm^{-1}) can be confidently assigned to the O–H stretch group. A sharp band exists for the stretching frequency of O–H for the IR spectrum of O–H containing systems as delineated in the following text: primary alcohols (–CH_2–OH) exhibit fundamental stretching vibration of (O–H) = 2740 nm (3650 cm^{-1}), 1397.4–1507.0 nm (first overtone), 940.7–1050.3 nm (second overtone), and 712.4–822.0 nm (third overtone); secondary alcohols (R–CHOH–R′) exhibit fundamental stretching vibration of (O–H) = 2762 nm (3620 cm^{-1}), 1408.6–1519.1 nm (first overtone), 948.3–1058.8 nm (second overtone), and 718.1–828.6 nm (third overtone). Tertiary alcohols (R–CR′OH–R″) demonstrate fundamental stretching vibration of (O–H) = 2770 nm (3610 cm^{-1}), 1412.7–1523.5 (first overtone), 951.0–1061.8 nm (second overtone), and 720.2–831.0 nm (third overtone). Phenols fundamental stretching vibration of (O–H) = 2762–2793 nm (3620–3580 cm^{-1}), 1408.6–1519.1 nm (first overtone), 948.3–1070.7 nm (second overtone), and 718.1–837.9 nm (third overtone). Carboxylic acids have fundamental stretching vibration of (O–H) = 2817–2857 nm (3550–3500 cm^{-1}), 1436.7–1571.4 nm

(first overtone), 967.2–1095.2 nm (second overtone), and 732.4–857.1 nm (third overtone).

To distinguish between primary, secondary, and tertiary alcohols using IR spectra requires the use of these bands as well as the fundamental stretching vibration of (C−O) at 8547–9615 nm (1170–1040 cm^{-1}), 4903.7–5288.3 nm (first overtone), 3301.2–3685.8 nm (second overtone), and 2499.9–2884.5 nm (4 n); this band is not observed in the NIR region. The O−H in-plane fundamental bend occurs as (O−H) at 7143–7692 nm (1400–1300 cm^{-1}), 3642.9–4230.6 nm (first overtone), 2452.4–2948.6 nm (second overtone), and 1857.2–2307.6 nm (third overtone). The C−O−H out-of-plane fundamental bend as (O−H) occurs at 13 158–15 385 nm (760–650 cm^{-1}); it is not observed in the NIR. Carboxylic acids (−COOH) form dimers (hydrogen bonding between molecules as (−C=O···H−O−C−) in condensed states that exhibit four distinct frequencies: (1) a very broad, very strong O−H stretch at approximately 3333 nm (3000 cm^{-1}, at a lower frequency than alcohols), 1699.8–1833.2 (first overtone), 1144.3–1277.7 (second overtone), and 866.6–999.9 nm (third overtone); (2) summation tones as one to three weak bands near 3846 nm (2600 cm^{-1}), 1961.5–2115.3 nm (first overtone), 1320.5–1474.3 nm (second overtone), and 1000–1153.8 nm (third overtone); (3) carbonyl (C=O) stretch vibration near 5797 nm (1725 cm^{-1}), 2956.5–3188.4 nm (first overtone), 1990.3–222.2 nm (second overtone), 1507.2–1739.1 nm (third overtone); (4) a weak broad band indicating a dimer condition near 10 471 nm (955 cm^{-1}) is not observed in the NIR.

4.11 N−H Group Frequencies and Nitrogen-containing Compounds

The average frequencies for free N−H groups include those given in detail in the following paragraph.

Amide groups include primary amides, −(C=O)−NH_2, fundamental stretching vibration of (N−H) = 2857 nm (3500 cm^{-1}), 1457.1–1571.4 nm (first overtone), 980.9–1095.2 nm (second overtone), 742.8–857.1 nm (third overtone). For primary amides a band also occurs at 2933 nm (3410 cm^{-1}), 1495.8–1613.2 nm (first overtone), 1007.0–1124.3 nm (second overtone), and 762.6–879.9 nm (third overtone); and secondary amides, −(C=O)−NHC, fundamental stretching vibration of (N−H) = 2899 nm (3450 cm^{-1}), 1478.5–1594.5 nm (first overtone), 995.3–111.3 nm (second overtone), 753.7–869.7 nm (third overtone).

Alkyl (aliphatic-NH-X) groups include alkyl-NH_2, fundamental stretching vibration of (N−H) = 2946 nm (3395 cm^{-1}), 1502.5–1620.3 nm (first overtone), 1011.5–1129.3 nm (second overtone), and 766–883.8 nm (third overtone); and 3003 nm (3330 cm^{-1}), 1531.5–1651.7 nm (first overtone), 1031.0–1151.2 nm (second overtone), and 780.8–900.9 nm (third overtone); alkyl-NH-X, fundamental stretching vibration of (N−H) = 2981 nm (3355 cm^{-1}), 1520.3–1639.6 nm (first overtone), 1023.5–1142.7 nm (second overtone), 775.1–894.3 nm (third overtone).

For aryl (aromatic-NH-X) groups, the N−H stretch fundamentals occur as aryl-NH_2, fundamental stretching vibration of (N−H) = 2869 nm (3485 cm^{-1}), 1463.2–1578.0 nm (first overtone), 985.0–1099.8 nm (second overtone), and 745.9–860.7 nm (third overtone); and a second band is found near 2946 nm (3395 cm^{-1}), 1502.5–1620.3 nm (first overtone), 1011.5–1129.3 nm (second overtone), and 766–883.8 nm (third overtone). Aryl-NH-X, fundamental stretching vibration of (N−H) = 2911 nm (3435 cm^{-1}), 1484.6–1601.1 nm (first overtone), 999.4–1115.9 nm (second overtone), 756.9–873.3 nm (third overtone). Note that the N−H frequency is lower and less intense than the O−H frequency; the hydrogen-bonding effects for N−H are weaker and of less effect than in O−H.

Primary amines (R−NH_2) demonstrate two N−H stretching bands due to coupling: the in-phase (or symmetric), and the out-of-phase (or asymmetric); aliphatic amines, (C_nH_{2n+1})-NHX, demonstrate medium strength in-phase frequencies at 2999–3053 nm (3335–3275 cm^{-1}), 1529.5–1613.2 nm (first overtone), 1029.7–1124.3 nm (second overtone), and 779.7–879.9 nm (third overtone). The out-of-phase medium strength frequency occurs at 2933–2985 nm (3410–3350 cm^{-1}), 1495.8–1641.8 nm (first overtone), 1007.0–1144.3 nm (second overtone), 762.2–895.5 nm (third overtone).

Aromatic amines exhibit two medium strength frequencies, an in-phase frequency at 2920–3003 nm (3425–3330 cm^{-1}), 1489.2–1651.7 nm (first overtone), 1002.5–1151.2 nm (second overtone), and 759.2–900.9 nm (third overtone), and an out-of-phase frequency at 2849–2950 nm (3510–3390 cm^{-1}), 1453.0–1622.5 nm (first overtone), 978.2–1130.8 nm (second overtone), 740.7–885.0 nm (third overtone). The scissoring for primary amines occurs as a medium to strong broad band at 6042–6289 nm (1655–1590 cm^{-1}), 3081.4–3459.0 nm (first overtone), 2074.4–2410.8 nm (second overtone), and 1570.9–1886.7 nm (third overtone). The NH_2 wagging is a strong broad band near 12 500 nm (800 cm^{-1}) and is not observed in the NIR region.

Secondary amines (R′R″−NH) exhibit a single broad N−H stretch vibrational frequency near 3021 nm (3310 cm^{-1}), 1540.7–1661.6 nm (first overtone), 1037.2–1158.1 nm (second overtone), and 785.5–906.3 nm (third overtone). An N−H bend occurs as a weak-to-medium strength band near 6667 nm (1500 cm^{-1}), 3400.2–3666.9 nm (first overtone),

2289.0–2555.7 nm (second overtone), 1733.4–2000.1 nm (third overtone).

To separate spectral features for the various amines, that is primary, secondary, and tertiary, it is helpful to point to obvious differences between the groups. For example, the number of N–H stretches for the three types are primary (2), secondary (1), and tertiary (0). For N–H bending vibrations, primary amines have a band near 6042–6289 nm (1655–1590 cm^{-1}); secondary amines, near 6667 nm (1500 cm^{-1}); and this feature is absent in tertiary amines.

The C–H stretch vibration for CH_2 is to be found for all three types of amines from 3503 to 3683 nm (2855–2715 cm^{-1}), 1786.5–2025.7 nm (first overtone), 1202.7–1411.8 nm (second overtone), and 910.8–1104.9 nm (third overtone). For primary amines, the C–H stretch will be found at higher frequencies nearer to 3448 nm (2900 cm^{-1}), 1758.5–1896.4 nm (first overtone), 1183.8–1321.7 nm (second overtone), and 896.5–1034.4 nm (third overtone).

Amine salts as $R-NH_3^+$ and $R'R''NH_2^+$ exhibit several weak bands near 3571–4545 nm (2800–2200 cm^{-1}), 1821.2–2499.8 nm (first overtone), 1226.0–1742.3 nm (second overtone), 928.5–1363.5 nm (third overtone). These salts exhibit a weak-to-medium, very broad band, centered near 4000 nm (2500 cm^{-1}), 2040–2200 nm (first overtone), 1373.3–1533.3 nm (second overtone), and 1040.0–1200 nm (third overtone). This broad band is lower in frequency than the C–H stretch and up to 314 nm (500 cm^{-1}) in width at the baseline.[33]

4.12 Amines (R–NH–X)

Amines are polar compounds, and both primary and secondary amines can form intermolecular hydrogen bonding. All classes of amines are water soluble (up to six carbon atoms) and will form hydrogen bonding in aqueous solutions. NIR absorptions for amines occur in decreasing wavelength order as:

- 2020 nm — primary N–H combination band
- 2000–2050 nm — N–H stretch and N–H bend combination band
- 1990–2020 nm — free and bonded primary amines
- 1960 nm — combination of N–H stretch and NH_2 bending, for example meprobamate
- 1500–1550 nm — primary amines first overtone aliphatic N–H stretch
- 1530 nm — N–H stretch overtone for aliphatic-NH system
- 1450 nm — cyclic amines, e.g. pyrroles, indoles, and carbazoles show intense first overtone N–H stretch
- 1010–1020 nm — aliphatic (alkyl-) N–H stretch second overtone
- 995–1015 nm — aromatic (aryl-) N–H stretch second overtone.

Whetsel[7] provided NIR spectra for primary aromatic amines. He provides spectra for aniline and 39 of its ring-substituted derivatives, giving special attention to N–H bands located between 1000 and 2000 nm.

4.13 Amides (–C=O–NX′X″, also shown as –NHCO–)

Amide absorptions are as follows:

- 2817–3279 nm — fundamental N–H for acyl- group of amide (3550–3050 cm^{-1}) as (R–C=O–)
- 5917–6061 nm — the C=O stretch fundamental (1690–1650 cm^{-1})
- 2000 nm (5000 cm^{-1}) — combination band
- 1500 nm (6667 cm^{-1}) — first overtone
- 1000–1050 nm — primary amides (–C=O–NH_2)
- 1450–1500 nm — primary amides
- 2850–2950 nm — primary amides

5 POLYMERS

5.1 Types of Polymer

Polymers are large molecules consisting of repeating units. The repeating units are referred to as monomers. Natural polymers exist such as starches and polysaccharides. Synthetic polymers are commonly termed plastics and are used for myriad products. Polymers vary in molecular formula and molecular weight due to variation in the number of repeating units. Polymer backbone structures often have attached molecular groups. The molecular arrangement of these groups determines the stereochemical configuration for any given polymer. If all the attached groups are in the identical position along the polymer backbone chain the polymer is in an *isotactic* configuration. If the attached groups alternate in their attached positions with a regular pattern the *syndiotactic* configuration is ascribed. When attached groups are randomly attached to the polymer backbone the polymer is

Figure 5 Natural product polymers exist as proteins (amino acid polymers), cellulose (carbohydrate polymers) with high molecular weights, and starches (carbohydrate polymers with intermediate molecular weight). The NIR spectrum shown is that of a plant starch (32 cm^{-1} resolution).

said to have an *atactic* configuration. The isotactic configuration represents the most crystalline (rigid) of the configuration types.

Copolymers involve the use of two or more monomer types in a single backbone structure to achieve specific material performance properties. Structures are classified as *alternating* (–A–B–A–B–A–B–), *random* (–A–A–B–A–B–B–A–), *block* (–A–A–B–B–B–B–A–A–), and *graft* (–A–A–A–A–A–A–A–).

B B
B B

Polymerization involves the reaction of the monomer building blocks to make polymers. The polymerization reaction types involve *addition* reactions and *condensation* reactions. Addition reactions typically involve the use of ethene to form polyethene and polyethylene. Condensation reactions typically involve different reaction products reacting to form a heteropolymer and a small molecular by-product. The reaction of 1,6-diaminoethane and hexanedioic acid to form nylon and water is a classic example. Polymers made from one monomer type are termed *homopolymers* and those formed from two different monomers are referred to as *copolymers*.

Typical structures of polymers and their respective NIR spectra are shown.

Dacron **(1)** is a polyester of ethylene glycol and terephthalic acid, known as 'Mylar'. Delrin **(2)** is a paraformaldehyde polymer. Melmac or Bakelite **(3)** is a phenolic copolymer with formaldehyde. Molecular structure **(4)** is a ureaformaldehyde resin.

Typical polymer spectra exhibit similar NIR bands and positions which are represented by the chart in Table 5.

5.3 Qualitative Analysis of Polymers

Qualitative polymer analysis using NIR spectroscopy involves the identification or verification of unknown substances for quality control and problem solving; and the measurement of reactants and reaction products during batch reactions; and the determination of degree of mixing and of quality index of manufactured products. Identification or verification of an unknown material involves sampling the unknown, measuring the NIR spectrum of the material, and comparing the resultant spectrum to a standard library of known spectra. The

Figure 7 NIR spectrum of atactic poly(propylene) at 32 cm^{-1} resolution.

Figure 8 NIR spectrum of the poly(propylene) plus poly(ethylene) copolymer at 32 cm^{-1} resolution.

method of comparison often termed *spectral matching* or *spectral searching* is described in more detail within section 7 of this article. Once the unknown is identified the spectrum from it can be archived for future retrieval and comparison, or simply retained for quality reasons.

Measurement of reactants during processing is accomplished for polyethylene and polypropylene (olefins) production by measuring the solution polymerization mixture for the disappearance of double bonds from the polyethene materials. Workers have reported the occurrence of a terminal double bond combination band at 2110 nm and a first overtone band at 1620 nm.[9] Note that the NIR technique is useful for measuring the ratios of methyl, methylene, and methine (weak) groups although their location within the polymer structure cannot be determined using this technique. Proton NMR would prove to be more useful if configuration studies were required.

Activators in condensation reactions can be monitored using NIR when the reactants are in a liquid form. During the production of PVC the activator molecules can be monitored. IR-active reactants and reaction products are often monitored using NIR. The solids content or degree of conversion for organic molecules can be monitored as the reaction progresses. This type of measurement allows reaction kinetic studies or end-point monitoring.

Figure 9 NIR spectrum of atactic poly(styrene) at 32 cm^{-1} resolution.

Figure 10 NIR spectrum of crystalline poly(styrene) at 16 cm^{-1} resolution.

Degree of mixing in a batch reaction is determined by monitoring a point or multiple points within a mixing chamber for a change in spectral signal. When the mixing is just beginning there will be large spectral variation; after the materials are well mixed the measured spectral variations will become slight. When the components are well mixed the spectral variation during further mixing will be unchanged.

The determination of the quality index of manufactured products is accomplished using spectral searching or comparison. A library of high-quality finished product spectra are maintained for comparison purposes. The sample to be tested is compared during the manufacturing process to the reference library set. When the predetermined match index (MI) value is achieved during manufacturing, the quality index is recorded. Further testing is sometimes completed for verification purposes, but the concept of rapid nondestructive quality index measurement allows more efficient production costs with higher quality products.

5.4 Quantitative Analysis of Polymers

Quantitative analysis of polymers involves the use of classic spectroscopic quantitative practices or the use of multivariate calibration methods described in section 7. The technique is useful in the production of many polymers as a quantitative monitoring of reactants and reaction products during the manufacturing process. The polymerization process can be optimized for specific yields of reaction products using quantitative methods. The literature describes NIR methods for monitoring or measuring components from a variety of polymerization reactions including polyolefins, polyesters, paraformaldehydes,

Figure 11 NIR spectrum of poly(acrylic acid) at 32 cm^{-1} resolution.

Table 5 Spectral correlation for polymers

Polymer	Band location (nm)	Band assignment

phenolics, natural products (polysaccharides), chloroprenes, polyamides, acrylonitriles, polystyrenes, polyfluorocarbons, and polyacrylates. Kradjel and McDermott[9] describe analytical parameters for measurements in olefin production, PVC, PVA, polyvinyl acetate, polystyrene, acrylic and methacrylic polymers, polyamides, cellulose esters, starch, alcohols, polyurethanes, polyesters, epoxy resins, phenolics, and melamine formaldehydes.

6 RUBBERS

6.1 Types of Rubber

Rubber or elastomer is a natural or synthetic material having the ability to undergo deformation under the influence of an applied force and regain its original shape once the applied force is removed. Natural rubbers are polymeric materials originally obtained from the rubber tree (*Hevea brasiliensis*). The sap of this tree is a latex material which is processed by coagulation and drying the sap, and then vulcanizing and adding filler compounds. The basic natural rubber compound is isoprene which contains the repeating unit of $-CH_2C(CH_3):CHCH_2-$. Synthetic rubbers exist such as nitriles, butadienes, neoprene, butyl rubbers, polysulfide rubbers, PVC, and silicone rubbers whose structures and NIR spectra are shown.

Structures **(15)** (*trans* form) and **(16)** (*cis* form) show typical repeating units found in natural rubber (isoprene). Structure **(17)** shows a repeating unit of nitrile rubber.

Structure **(18)** is a monomer unit of *cis* or *trans* polybutadiene rubber and structure **(19)** is a repeating unit of neoprene rubber. Structure **(20)** is a monomer unit of butyl rubber and **(21)** is a repeating unit of synthetic natural rubber (*z*-polyisoprene). Structure **(22)** shows the general formula for polysulfide rubbers where R represents −C−C, −C−C−O−C−C, or −C−C−O−C−O−C−C− groups. Structure **(23)** is a building block of PVC. The methyl group in silicone rubbers (polysiloxane) **(24)** is often substituted with a variety of alkyl groups. Structure **(25)** shows SB (styrene–butadiene) rubber. Urethane rubbers **(26)** are depicted where R and R′ are −C− and −C−C−.

Figures 12–14 shows the NIR spectra of styrene, ethylene butylene, styrene copolymer, styrene–isoprene–styrene and silicone DMS, respectively.

6.3 Qualitative Analysis of Rubbers

Rubber analysis can be completed using NIR spectra for verification of rubber quality and type. This analytical method utilizes spectral searching methods as described in section 7 with comparisons against known quality reference standards. Batch mixing conditions and reaction kinetics are also measured using NIR. The description of qualitative techniques found in section 5.3 describes some of the general methods used for rubber (or elastomer) measurements. Final product quality and evaluation is becoming a more common practice for qualifying polymer and elastomer production quality.

The traditional use of molecular spectroscopy for qualitative analysis of elastomeric materials involved the use of IR microspectroscopy. This technique was

Figure 12 NIR spectrum of styrene, ethylene butylene, styrene copolymer at 32 cm^{-1} resolution.

Figure 13 NIR spectrum of styrene–isoprene–styrene at 32 cm^{-1} resolution.

used for analysis of minute amounts of material for forensic or synthetic organic chemistry. This technique is still used for cases involving a small quantity of analyte. Samples as small as 5–20 μm can be measured using microspectroscopic techniques. The use of NIR for assignment of functional groups present in an unknown compound is generally not performed. For identification of the presence of various functional groups, FTIR and Raman spectroscopy are generally employed due to the greater sensitivity and resolution associated with these techniques (see section 8 for further details). NIR can be used for bulk qualitative analysis when sample identification or qualification are necessary.

6.4 Quantitative Analysis of Rubbers

As is described in detail in section 4 of this article, functional groups containing C–H, N–H, and O–H within elastomer compounds are most easily characterized using NIR spectroscopy. The stretching vibrations of these molecules can generally be quantified using multivariate calibration and NIR spectra as described in section 7. The unique attributes of an NIR spectrum

	1400	C−H stretch mode combination
	1719	Asymmetric methylene (C−H) stretch – first overtone + aromatic C−H stretch – first overtone
	2171	C−H bend – second overtone
	2291	C−H stretch + CH_2 deformation combination
	2336	C−H stretch + CH_2 deformation combination
	2470	C−H stretch + C−C stretch + C−O−C stretch combination
Silicone (DMS)	1452	Si−O stretch – first overtone
	1748	Methyl (C−H) stretch – first overtone
	1933	Si−O−H stretch + Si−O−Si deformation combination
	2295	C−H bend – second overtone

allow quantification of carbon–carbon double bonds, methyl, methylene, and methine (in some cases) carbon–hydrogen stretching. Bands due to the N−H stretch of amines and amine salts are also measurable. Carbonyl C=O stretch and associated C−H stretch are also quantifiable, as is information from the C−O−C and C−C stretching vibrations. A large signal is obtained when measuring O−H, H−O−H, O−Si and Si−O−Si stretching vibrations. With this basic knowledge the analyst can determine the appropriate spectral regions for measuring reactants and reaction products before, during, and after the elastomeric forming reaction(s). The tables and reference spectra demonstrated in this article are useful for identifying the appropriate spectral regions.

7 METHOD DEVELOPMENT

Method development for NIR spectroscopy in the analysis of polymers and rubbers often involves the use

of chemometrics. Chemometrics as it pertains to NIR spectroscopy involves the preprocessing of spectroscopic measurement data to maximize the signal-to-noise characteristics and the use of multivariate calibration algorithms to develop predictive or comparative models for analysis. Method development for polymer and rubber analysis involves the generalized steps described in the following text for both qualitative and quantitative analysis.

7.1 Qualitative Analysis

The ''alikeness'' of one test polymer spectrum (or series of spectra) to a reference set of polymer spectra can be determined by calculating a point-by-point correlation between absorbance data for each test and reference spectrum. The correlation matching can be accomplished for all data points available or for a preselected set only. The more alike the test and reference spectra are, the higher (closer to 1.00) are the r (correlation coefficient) and R^2 (coefficient of determination) values. A perfect match of the two spectra would produce r or R^2 values of 1.00000. The sensitivity of the technique can be increased by pretreating the spectra first to higher order derivatives and then calculating the correlation between the test and reference spectra. Full spectral data can also be truncated (or reduced) to include only spectral regions of particular functional group interest, a practice which will further improve matching sensitivity for a particular spectral feature of interest.

7.2 General Qualitative Practices

The ASTM (American Society for Testing and Materials) has published a *Standard Practice for General Techniques for Qualitative Analysis* (Method E 1252-88). The method[34] describes techniques useful for qualitative evaluation of liquids, solids, and gases using the spectral measurement region of $4000–50\,cm^{-1}$ (above 2500 nm). A revised method is being drafted to encompass the newer chemometrics techniques in current research practice.[35] Several primary references describe the use of this mathematical approach.[36–39]

7.3 Spectral Searching

Techniques for searching and matching test spectra include the use of Mahalanobis distance[36–39] and cross-correlation techniques (correlation matching) described above. The general method for comparing two spectra (test versus reference), where the reference is a known compound, or the mean spectrum of a set of known spectra, is given as the MI. The MI is computed by comparing the vector dot products between the test and reference spectra. The theoretical values for these dot products range from -1.0 to $+1.0$, where -1.0 is a perfect negative (inverse) correlation, and $+1.0$ is a perfect match. Since for NIR spectroscopy only positive absorbance values are used to compute the dot products, the values for the MI must fall within the 0.0 to $+1.0$ range. The method, or variations thereof, is described in the literature.[40–44] The mathematics are straightforward and are given below.

The MI is equal to the cosine of the angle (designed as α) between two row vectors (the test and reference spectra) projected on to a two-dimensional plane, and is equivalent to the correlation (r) between the two spectra (row vectors), Equation (15)

$$\mathrm{MI} = \cos\alpha = \frac{T \bullet R}{|T||R|} \tag{15}$$

where T is the test spectrum row matrix, and R is the reference spectrum row matrix.

Note the following, Equation (16)

$$T \bullet R = \sum_{i=1}^{n} T_i R_i \tag{16}$$

where T_i represents the individual data points for the test spectrum (designated as the absorbance values of spectrum T from wavelengths $i = 1$ through n), and R_i represents the individual data points for the reference spectrum (designated as the absorbance values of spectrum R from wavelengths $i = 1$ through n) and where, Equation (17)

$$|T||R| = \left(\sum_{i=1}^{n} T_i^2\right)^{\frac{1}{2}} \left(\sum_{i=1}^{n} R_i^2\right)^{\frac{1}{2}} \tag{17}$$

Note the angle (α), in degrees, between two vectors can be determined from the MI using, Equation (18)

$$\alpha = \cos^{-1}(\mathrm{MI}) \tag{18}$$

7.4 Near-infrared Quantitative Calibration

When NIR spectroscopy is applied as a quantitative analysis technique a computer is used to collect the measurement data, to calculate multivariate calibration models, and to apply those models to the prediction of the chemical composition of unknown samples. Table 7 describes the general quantitative calibration procedures. Sample sets are selected for teaching, model validation, and analyzer monitoring control. The purpose of the calibration model is to relate the concentration of some analyte found in a sample to the spectral data collected from that sample. The teaching sets must be comprised of a wide survey of sample chemistries as well as a variety of instrument response types. The instrumental artifacts are convoluted into the NIR spectra, and thus unless

Table 7 Critical procedures in calibrating (and maintaining) an NIR spectrophotometer

1. Selecting the calibration set using experimental design criteria.
2. Determination and verification of standard concentrations using verifiable reference methods.
3. Collection and verification of optical response data.
4. Final validation for the integrity of X-block (instrument) and Y-block (reference) data.[47–49]
5. Optimization for data preprocessing method.
6. Calibration modeling.
7. Statistical validation of the calibration model.
8. Routine analysis and calibration monitoring (using outlier statistics and monitoring samples).
9. Calibration model updating for sample or instrument changes.
10. Calibration model transfer optimization.

instruments have identical response across systems (or following major repair) the instrument function must be considered when developing a calibration model.

The complexity of calibration is dependent upon sample and instrument complexity, as well as the desired model performance. There is generally a trade between calibration performance and calibration robustness. Robustness here refers to the characteristic of a calibration where it can be transferred to other instruments (or to the same instrument after repair) without loss of performance. The use of multivariate quantitative analysis to describe the relationships between the concentration of an analyte and its NIR instrument response (viz. absorbance, T, transflectance, or reflectance) is common practice in analytical chemistry.[45] The practice of relating spectrophotometric response to concentration has been accomplished for a number of applications using Beer's law combined with C-matrix, K-matrix, MLR (multiple linear regression), PCR (principal components regression), PLSR (partial least squares regression), LWR (locally weighted regression), and NN (neural networks). Each application, and each set of experimental conditions, will produce slight differences in the selection of calibration channels (due to instrument response) as well as the weighting vectors (or coefficients) used for the final calibration model.

The use of NIR and chemometrics for *official* analytical methods is still in its early stages. The ASTM has adopted *Standard Practices for IR, Multivariate, Quantitative Analyses (Practice E1655-98)*,[34] which describes the peer-reviewed use of chemometrics for calibrating IR and NIR instruments. The perceived "barriers" to a more rapid deployment of chemometrics-based spectroscopy for chemical analysis include (1) a broad-based natural resistance to newer technologies, (2) the technical complexity and non-intuitive nature of chemometrics, and (3) difficulty in implementation (and maintenance) of chemometric methods. Since many of the calibration techniques are nonautomated, they require continuous expert manual labor for maintenance; this is accomplished through highly skilled chemometricians and application scientists. Table 7 shows the steps required to establish and maintain NIR quantitative methods.

7.5 Laboratory Methods

Typical laboratory methods for polymer and rubber analysis include chromatographic techniques, thermal analysis, microscopy, elemental, structural, rheometry, and various chemical identification tests. Many of these methods which relate directly to the presence of molecular functional groups can be measured using NIR spectroscopy. It is important to remember in laboratory analysis of polymer components that NIR is a correlation technique which can relate chemical or physical property information to NIR spectra. The capability of NIR to predict polymer components accurately depends on the true correlation between the measured physical or chemical property within a sample and that sample's NIR spectrum.

Most NIR techniques can be applied either at-line (near the actual manufacturing point), on-line (automated and at the manufacturing site), or in situ (measured in site or where a reaction or chemical/physical phenomenon is occurring). Moving a NIR measurement technique from the laboratory to the production line can be accomplished using remote measurement optics, such as specially configured optical collection heads or fiber optic cables or bundles. These will be discussed briefly in the next two sections.

7.6 At-line Measurements

At-line measurements involve taking the analytical measurement(s) using a dedicated and ruggedized spectrophotometer very near the production line, reaction vessel, or batch mixer. The advantage of having the measurement at the line is that rapid information used for making manufacturing decisions becomes readily available in time to make process adjustments related to quality and production efficiency. Slower laboratory measurements are available only after the fact and do not enable real-time adjustments during the process.

7.7 Process and On-line Measurements

Process analyzers are associated with such terms as airborne, at-line, automatic/automated, fieldable, hyperspectral, imaging/image analysis, in situ, in-line, near-line, noninvasive/nondestructive, on-line, open path, portable/hand-held, process monitoring/production control, quality control/quality assurance, quality monitoring,

rapid, real-time, and remote. In this discussion the term on-line is referred to as a NIR measurement made on the manufacturing process during production. The on-line measurement provides real-time or near real-time information for control of manufacturing parameters during production. On-line measurements are often made for batch reactions of most polymer products including glycols, polymers, polymer oxidation reactions, polymer mixing, polyolefin production, polyurethane foam manufacturing, polyether urethanes, polyethylene terephthalate, and biotechnology-related polymers.

8 COMPARISON OF NEAR-INFRARED WITH INFRARED AND RAMAN SPECTROSCOPY

NIR spectroscopy is used where multicomponent molecular vibrational analysis is required in the presence of interfering substances. The NIR spectra consist of overtones and combination bands of the fundamental molecular absorptions found in the MIR region. A detailed description of NIR spectral bands is given by Workman.[46] NIR spectra consist of generally overlapping vibrational bands that are nonspecific and poorly resolved. Chemometric mathematical data processing can be used to calibrate in quantitative analysis despite these apparent spectroscopic limitations. Traditional NIR spectroscopy was used in agricultural product analysis for lignin polymers (2270 nm), paraffins and long-alkane chain polymers (2310 nm), glucose-based polymers such as cellulose (2336 nm), amino acid polymers as proteins (2180 nm), carbohydrates (2100 nm), and moisture (1440 and 1940 nm).

Dominant NIR spectral features include the methyl C−H stretching vibrations, methylene C−H stretching vibrations, aromatic C−H stretching vibrations, O−H stretching vibrations, methoxy C−H stretching, and carbonyl associated C−H stretching. In addition, N−H from primary amides, secondary amides (both alkyl and aryl group associations), N−H from primary, secondary, and tertiary amines, and N−H from amine salts predominate in NIR spectral features for polymers and organic compounds.

MIR spectroscopy provides a measurement technique for intense, isolated and reliable absorption bands of fundamental molecular vibrations from polymers and other organic compounds. The spectrometric methodology allows for univariate calibration with higher signal strength (absorptivities) required for solid, liquids or gas phase measurements. Relatively small pathlengths of 0.1–1.0 mm are required for hydrocarbon liquids and solids. The technique is generally incompatible with the use of fiber optics, but specialized fiber materials exist. Instrumentation costs more than NIR spectrophotometers for the most part.

Dominant MIR spectral features include the C−H (methyl, methylene, aromatic, methoxy, and carbonyl) fundamental stretching and bending molecular vibrations, O−H (hydroxyl) stretch fundamental vibrations, N−H (amine) stretching, C−F (fluorocarbon) stretching, −C=N (nitrile) stretching, −C=O (carbonyl) stretch from esters, acetates, and amides, C−Cl stretch from chlorinated hydrocarbons, and $-NO_2$ from nitro-containing compounds.

Raman spectroscopy can be used for a variety of measurements on samples that are aqueous in nature or where glass sample holders are present. Carbon dioxide, water, and glass (silica) are weak scatterers and thus there is generally no problem in analyzing samples that have these properties. There is typically no sample preparation involved in samples measured using Raman spectra. Raman spectroscopy is complimentary to MIR spectroscopy in the measurement of fundamental molecular vibrations. Raman measurements are compatible with fiber optics. Raman measurements exhibit high signal-to-noise and represent a reasonable cost for instrumentation. The dominant Raman spectral features are acetylenic C=C stretching, olefinic C=C stretch at 1680–1630 cm^{-1}, N=N (azo-) stretching, S−H (thio-) stretching, C=S stretching, C−S stretching, and S−S stretching bands. Raman spectra also contain such molecular vibrational information as CH_2 twist and wagging, carbonyl C=O stretch associated with esters, acetates, and amides, C−Cl (halogenated hydrocarbons) stretching, and $-NO_2$ (nitro-/nitrite) stretching. In addition, Raman yields information about phenyl-containing compounds at 1000 cm^{-1}.

The neutron is in many ways an ideal probe for the investigation of the structure and dynamics of materials. Elastically scattered neutrons can be used to determine the structure of the sample from the atomic to macromolecular length scales, whilst dynamic information describing the vibration, rotation and translation of these molecules is obtained from inelastically scattered neutrons. The use of isotopic substitution provides an easy route to highlighting whole or parts of a molecule in the neutron scattering experiment. Isotopic labeling has been extensively used in polymer studies owing to the large difference between hydrogen and deuterium. The combined use of neutrons often with isotopic labeling schemes has provided a wealth of detailed information about polymer materials, which could not be derived so easily by other methods.

1 INTRODUCTION

Neutrons have been used widely in scattering experiments to elucidate not only the structure but also the dynamics of materials. The neutron scattering techniques that have been generally applied to study polymeric material include small-angle neutron scattering (SANS) and wide-angle neutron scattering (WANS), neutron reflection (NR), quasielastic neutron scattering (QENS) and inelastic neutron scattering (INS) and neutron spin-echo (NSE). These techniques can each provide different information about the material. Elastic scattering (WANS, SANS and NR) provide structural and compositional information, whereas inelastic scattering techniques (QENS, INS and NSE) allow determination of molecular motion. In many ways therefore the neutron is an ideal probe for materials studies. The neutrons used for these studies have wavelengths given by de Broglie's relationship, $\lambda = h/mv$, where $m = 1.6 \times 10^{-27}$ kg, and v is the neutron velocity. With v of the order $10^3\,\mathrm{m\,s^{-1}}$ this gives neutron wavelengths of order 10^{-10} m (i.e. 1 Å), which is comparable to atomic dimensions allowing the possibility of structural determination on molecular length scales. The energies of the neutron equal to $\frac{1}{2}mv^2$ are of the order $k_\mathrm{B}T$, i.e. in the meV (10^7–10^{15} Hz) regime. This dynamic range allows the study of molecular rotation, vibration and translation and is comparable to the methods of infrared (IR), Raman or nuclear magnetic resonance (NMR) spectroscopy.

Although structural studies using neutrons covers the same spatial range provided by X-rays, the major difference in the techniques is in the interaction with the probing radiation and the sample. Unlike X-rays, which are scattered by the electron cloud surrounding the atom, neutrons are scattered either by the nucleus (nuclear scattering) or for the case of polarized neutrons also by the magnetic moment of unpaired electrons (magnetic scattering). The rest of this article will confine the discussion to nuclear scattering since magnetic scattering has not been widely exploited.[1–6] The strength of the neutron–nucleus interaction is characterized by the scattering length, b, which is not a function of atomic number but varies seemingly randomly across the periodic table. Of most interest to the polymer scientist is the difference between hydrogen and its isotope deuterium, which have large but different values of b ($b_\mathrm{H} = -3.739 \times 10^{-15}$ m and $b_\mathrm{D} = +6.671 \times 10^{-15}$ m). By deuterating parts or whole molecules, a huge contrast is produced between the labeled and unlabeled species. It is perhaps this property of the neutron above all others that has made neutron scattering such a powerful technique. The neutron is also highly penetrating and this has great advantages for the types of sample environment that can

Encyclopedia of Analytical Chemistry

be used. A number of useful engineering materials are almost transparent to the neutron, allowing the use of cryostats, pressure vessels, shear cells and simpler sample confinement systems to be used with little problems of beam loss or parasitic scattering. Finally, it should also be noted that unlike IR and Raman spectroscopy, owing to the neutron–nucleus interaction there are no selection rules which apply to INS.

Although there are only a limited number of facilities worldwide which can provide neutrons for research purposes, it may seem surprising to discover the vast wealth of literature describing results gained from neutron studies. However, neutron scattering has and continues to be arguably the only way to answer many fundamental and applied questions, in which case the amount of literature is not disproportionate with the number of instruments that allow such studies. In trying to summarize the huge amount of available literature on the use of neutrons in polymer studies, this article is necessarily limited to providing an overview, with a few examples by way of illustration. References to a large number of studies not mentioned directly in the text are given in a number of extended tables (see Tables 1–4). These are intended to provide a starting point for further literature searches because it has not been possible to provide a comprehensive list of all the available literature. Indeed, in the limited space available, it has also been necessary to limit the discussion and references mainly to polymers in the solid state. Further reading suggestions to general references and reviews have also been provided at the end of the article.

2 SOME BASIC CONCEPTS OF NEUTRON SCATTERING[7]

The features of a generalized neutron scattering experiment are shown in Figure 1.[8] The incident neutron beam is characterized in terms of a wavelength, λ_0, wavevector, κ_0, and energy, E_0. When passing through the sample, neutrons that are not absorbed are either transmitted without interaction or scattered via nuclei–neutron interactions. The scattered neutrons are analyzed in terms of their wavelength, λ, wavevector, κ, and energy, E. Both changes in direction of travel, $Q = \kappa - \kappa_0$, and energy, $\Delta E = E - E_0$, can occur. If the scattering process is elastic, then there is no energy change ($\Delta E = 0$) and only changes in direction of travel are observed. The momentum transfer, Q, is expressed by Equation (1):

$$Q = |Q| = \frac{4\pi}{\lambda} \sin \frac{\theta}{2} \tag{1}$$

where θ is the scattering angle. Therefore, elastic scattering only contains spatial information on the system.

If the scattering nuclei undergo motion with energies of the order of the neutron energies, then energy exchange between the neutron and nuclei may occur. In these circumstances the momentum transfer is now given by

Equation (2):

$$Q^2 = \kappa^2 + \kappa_0^2 - 2\kappa\kappa_0 \cos\theta \qquad (2)$$

and the energy change $\Delta E = (\hbar^2/2m)(\kappa^2 - \kappa_0^2)$. Neutrons which are scattered inelastically either gain or lose energy to the molecular motion. The energies associated with these motions are quantized, and in the case of vibrational motion the energy level spacing is large compared with the neutron energy. The changes in neutron energy are therefore observed as distinct peaks in the neutron energy spectra a distance equal to ΔE either side of the elastic peak (see Figure 2a). The difference in these inelastic peak intensities is due to the difference in occupancy of the two energy levels involved. The energy level spacings for rotational and translational motion are small compared with the neutron energy, which has the effect of broadening the elastic peak (see Figure 2b). Inelastic scattering therefore holds information not only about the spatial but also the dynamic character of the system.

The atomic scattering length, b, determines the amplitude of the wave scattered from a nucleus with respect to the amplitude of the incident wave. As seen for hydrogen

and deuterium, it is therefore possible to have both positive and negative values for b. A negative value indicates a half wavelength phase shift on scattering. Tabulated values of b can be found in the literature.[9,10] The square of the amplitude determines the probability that the neutron is scattered somewhere in space. With 4π sr in a sphere this probability is given by $4\pi b^2$, which is called the scattering cross-section, σ. The way in which the neutrons interact with the nuclei depends on their relative spins and type of isotope. This means that the total scattering cross-section of an assembly of nuclei, σ, is made up of coherent (σ_{coh}) and incoherent (σ_{inc}) cross-sections. The coherent scattering arises from interference effects between waves scattered from different nuclei and consequently contains all the structural information on the sample. The incoherent scattering, on the other hand, arises from scattered neutrons which are unaware of any correlation between nuclei. This means that incoherent scattering carries no structural information but is able to be exploited to study motion of atoms and molecules.

Experimentally, what is measured is the double differential scattering cross-section, $\partial^2\sigma/\partial\Omega\partial E$, which represents the number of neutrons scattered per second into a solid angle $d\Omega$ with an energy change between E and $E + dE$, with respect to the incident neutron flux. If the scattering is elastic (with no energy change) then the differential scattering cross-section, $\partial\sigma/\partial\Omega$, is measured. This is usually expressed as $d\Sigma/d\Omega$ (cm^{-1}), which is the scattering per sample unit volume.

2.1 Scattering and Structure

For elastic small-angle scattering the experimentally measured intensity, $I(Q)$, contains all the information on the size, shape and interactions between scattering nuclei. It is possible to write a generalized expression for SANS as in Equation (3):

$$I(Q) = c\frac{d\Sigma}{d\Omega}(Q) = cNV^2(\Delta\rho)^2P(Q)S(Q) + B \quad (3)$$

where c is a collection of instrumental- and sample-dependent constants,[11] N is the number concentration of scattering centers, V is the volume of one scattering center, $\Delta\rho = (N_i\Sigma b_i - N_j\Sigma b_j)$ is the contrast factor equal to the differences in scattering length densities, and B is the background signal and contains all the incoherent scattering intensity. By using isotopic substitution, where for instance H is replaced by D, the contrast between differing segments of a molecule or whole molecules can be enhanced. This enables the experimentalist to choose which part of the system is to be highlighted. The term NV^2 can be rewritten as $(\phi M)/(N_A\delta)$, where ϕ is the weight fraction, M is the effective molecular weight and

Figure 3 Plot of calculated form factor $P(Q)$ as a function of scattering vector illustrating the differences for sphere, a random coil and a rod-like structure. (Reproduced by permission from Arrighi et al.[8])

δ is the bulk density. The terms $P(Q)$ and $S(Q)$ are the form and structure factors, respectively, and contain all the structural information about the sample. The form factor, $P(Q)$, is related to the average conformation of an individual polymer chain. Model scattering functions have been developed for a variety of particle shapes, a number of which are shown in Figure 3. The structure factor, $S(Q)$, is a probability that the neutrons will be scattered as a function of Q.

The spatial range available with SANS varies between a few and thousands of ångstroms, making it ideal for studying both polymers and blends. The technique is not only suitable to studies of polymer blends in the homogeneous one-phase region, but can also be employed to investigate the kinetics of the phase separation process, the morphology of the two-phase systems which are formed as well as domain sizes. Owing to the length scales over which the polymer can be observed, different features of their size and shape manifest themselves in different regions of Q. It is therefore necessary to analyze the data in a number of ways in order to extract the data required. Many of the analysis methods used in SANS had been developed for small-angle X-ray scattering (SAXS) or light scattering (LS) and can be applied directly to SANS with only minor modifications. As discussed above, the major difference between neutron scattering and other techniques is the contrast between different species that can be induced by deuteration schemes.

The measured intensity in a scattering experiment is proportional to the differential scattering cross-section (see above). In very high Q regimes this is in turn related to the spatial Fourier transform of the atomic pairwise correlation functions. In the simple case of a system composed of identical nuclei, the differential cross-section in the elastic limit is given by Equation (4):

$$\frac{\partial\sigma}{\partial\Omega}(Q) = \sum_{i,j} b_i b_j \exp[iQ(\mathbf{r}_i - \mathbf{r}_j)] \tag{4}$$

where b_i and b_j are the scattering amplitudes of the nuclei in positions $\mathbf{r}_i$ and $\mathbf{r}_j$, respectively, and the angle brackets indicate an ensemble average. The double summation can be separated into self and pairwise terms. The self term contributes only to the incoherent background of the signal and contains no structural information and needs to be removed from the data to obtain the pairwise term, which contains all the structural information of interest. One way to remove the incoherent scattering is by use of deuteration but this is not always necessary.[12]

2.1.1 Single-phase Systems

For a one-phase system it can be shown generally that the form factor for low Q values can always be written as in Equation (5):

$$P(Q) = 1 - \frac{Q^2 R_g^2}{3} + \cdots \tag{5}$$

This relationship is valid for both rigid particles and flexible molecules and is an easy way to determine the size of the molecule. Arguably the two most important form factors for the polymer scientist are for a homogeneous sphere of radius R and that of a Gaussian segment distribution characterized by a radius of gyration, R_g. Assuming spherical geometry the scattering intensity given by Equation (3) can be written in terms of the Guinier approximation by Equation (6):

$$\frac{d\Sigma}{d\Omega}(Q) \approx NV^2(\Delta\rho)^2 \exp\left(-\frac{Q^2 R_g^2}{3}\right. \tag{6}$$

The radius of gyration is determined by the initial slope of a plot of $\ln[d\Sigma/d\Omega(Q)]$ versus Q^2 and the effective molecular weight from the intercept. Similar approximations also exist for a number of simple mathematical geometries such as discs, rods, stars and rings.[11] The closely related Zimm approximation also provides the means of obtaining the values of R_g and M from the initial slope and intercept $d\Sigma/d\Omega(Q)$ at $Q = 0$. The concentration dependence can also be incorporated into the Zimm approximation by including the second virial coefficient, A_2, giving Equation (7):

$$\frac{1}{\dfrac{d\Sigma}{d\Omega}(Q)} \approx \frac{1}{k_1 cM}\left(1 + \frac{Q^2 R_g^2}{3} \quad + 2A_2 k_2 c + \cdots \right. \tag{7}$$

Figure 4 Zimm plot of SANS data from a mixture of various concentrations of h-PMMA dissolved in d-PMMA. The open circles are the result of extrapolation to zero concentration and zero Q. (Reproduced by permission from Kirste et al.[13])

where $k_1 = (\Delta\rho)^2/(N_A\delta^2)$, $k_2 = 1/(k_1 c)$ and c is the concentration. A Zimm plot of $k_1 c/(d\Sigma/d\Omega)(Q)$ versus $c + \alpha Q^2$ where α is an arbitrary constant gives the radius of gyration from the ratio of the slope to intercept. Normally the scattering is collected from a number of sample concentrations and plotted in the Zimm format, extrapolation to zero concentration and Q allows determination of the molecular weight. This value is an important check on the validity of the scattering data. A nice example of this is shown in Figure 4 for low concentrations of hydrogenated (h) PMMA in a matrix of the fully deuterated form (d-PMMA).[13]

Debye demonstrated that the intermediate Q scattering from chains, which exhibit a Gaussian distribution of segment densities about a center of mass, such as observed for polymers in a theta state either in solution or in a melt, is given by Equation (8):[14]

$$\frac{d\Sigma}{d\Omega}(Q) \approx \frac{2NV^2(\Delta\rho)^2}{Q^2R_g^2} \tag{8}$$

A plot of $d\Sigma/d\Omega(Q)Q^2$ versus Q (called a Kratky plot) should asymptotically approach a plateau at high Q for chains which exhibit Gaussian statistics. Non-Gaussian chain behavior such as branched or star polymers produce characteristic deviations to a normal Kratky plot.[11,15,16]

2.1.2 Two-phase Systems

The scattering behavior arising from composition fluctuations in phase-separated polymer blends or copolymer melts can be interpreted in the context of the random phase approximation (RPA).[17] The scattering is therefore given by Equation (9):

$$\frac{1}{\dfrac{d\Sigma}{d\Omega}(Q)} = \frac{1}{(\Delta\rho)^2} \sum_i \frac{1}{n_i v_i \phi_i P(Q, R_{g,i})} + \frac{2\chi_{eff}}{\sqrt{v_1 v_2}} \Bigg\} \tag{9}$$

where n_i is the segment volume for polymers $i = 1$ or 2, v_i is the segment volume, ϕ_i is the volume fraction, χ_{eff} is the effective Flory–Huggins interaction parameter and the form factor is given by $P(Q, R_{g,i}) = 2[\exp(-Q^2R_{g,i}^2) + Q^2R_{g,i}^2 - 1](Q^2R_{g,i}^2)^{-2}$. In the low-$Q$ limit this reduces to an Ornstein–Zernicke function where $(d\Sigma/d\Omega)^{-1}(Q) \propto (Q\xi)^2$, where ξ is the average composition fluctuation length of the composition. Assuming randomly distributed two-phase systems of indefinite size and shape also allows ξ to be obtained from the Debye–Bueche function where $(d\Sigma/d\Omega)(Q) \propto \xi^3/(1 + Q^2\xi^2)^2$.

If the polymer blend consists of two phases with arbitrary shape and orientation but sharp boundaries, as may be expected in immiscible polymer blends, then the high-Q scattering decays as Q^{-4} in accordance with Porod's law as given by Equation (10):[18]

$$I(Q)Q^4 = \frac{c_p}{\rho_p} 2\pi(\Delta\rho)^2 \left(\frac{S_p}{V_p} \right. + I_{inc}(Q)Q^4 \tag{10}$$

where c_p is the particle concentration, ρ_p is the density of the particle, S_p/V_p is the surface area to volume ratio and $I_{inc}(Q)$ is the incoherent scattering which is observed as a flat nonzero background at high Q. As seen below, deviations from true Porod's law arise if the interphase region is diffuse and can be accounted for by suitable changes to Equation (10).

2.1.3 Interfaces and Surfaces

NR is an elastic scattering technique that measures the reflectivity, $R(Q)$, of thin-films and surfaces. $R(Q)$ is the ratio of reflected to incident intensity and is related to the Fourier transform of the scattering length density profile, $\rho(z)$, which is the scattering length density variation as a function of depth, z, perpendicular to the surface. In all but a very limited set of examples, where a kinematic approximation can be applied,[19] the $R(Q)$ data cannot be Fourier transformed into the desired $\rho(z)$ profile. Analysis is usually made by calculation of reflectivity profiles from models, where the thickness, scattering length density and interfacial roughness of each layer within the model are fitting parameters.[20] The reflectivity can be calculated exactly for any model using the equations of Fresnel in addition to those of Snell.[21–23] For all but the simplest case of an infinitely sharp interface between two bulk media, the application

of these equations becomes cumbersome and to aid computational speed matrix methods have been used for calculating reflectivity profiles.[21]

2.2 Molecular Motion and Dynamics

Noting that the neutron energy can be written in terms of angular frequency, so that $\Delta E = hw$, then the experimentally measured double differential scattering cross-section can be written according to Equation (11) in terms of a dynamic scattering structure factor, $S(Q, w)$:

$$\frac{\partial^2\sigma}{\partial\Omega\partial w} = \hbar\frac{\partial^2\sigma}{\partial\Omega\partial E} = \frac{\kappa}{\kappa_0}b^2 N_T S(Q, w) \tag{11}$$

where N_T is the ratio of volume of the sample to the volume of the scattering unit. The measured neutron intensity as a function of both Q and w, $I(Q, w) = c(\partial^2\sigma/\partial\Omega\partial w)$, contains information not only about the motions of the individual nuclei and their motion relative to one another, but also structural information contained within the elastic scattering component. The quasielastic broadening of the elastic peak arising from translational or rotational motion can be described in terms of a self-diffusion coefficient, D_s.[24–26] For a simple center of mass diffusion the scattering law is given by Equation (12):

$$S(Q, w) = \frac{\pi D_s Q^2}{w^2 + D_s^2 Q^4} \tag{12}$$

A Lorenzian shape with a half-width proportional to $D_s Q^2$ therefore describes the scattering. Departures from simple diffusion have also been proposed such as jump diffusion.[26]

Scattering from other motions can be described by models that specify the way in which cooperative disturbances are transmitted along the backbone. Such treatments based on the ideas of Rouse and Zimm use bead and spring models to represent the connectivity of the polymer chain.[27–30] The Rouse model assumes disturbances are transmitted along the chain and has been used to describe molecular motion in the melt. In the Zimm model, the presence of a surrounding medium, such as solvent molecules, via hydrodynamic interactions modifies the behavior of the chain segments. The Zimm model has had particular application in studies of polymers in solution.[31]

Another technique used to measure the dynamics of materials is NSE. This technique was conceived by Mezei[32] and utilizes the polarizable nature of the neutron through its spin ($I = 1/2$) to analyze molecular motion. In a magnetic field the polarized neutron will precess at the Lamor frequency. This Lamor precession is used as an internal clock to monitor the scattering process of the neutron and permits a very precise determination of the energy difference before and after scattering.[33] Any molecular motion is therefore directly observed by changes in the polarization, P, as given by Equation (13):

$$P = \frac{S(Q, t)}{S(Q, t_0)}\frac{\int_0^\infty I(\lambda)\,\mathrm{d}\lambda S(Q, w)\cos(wt)\,\mathrm{d}w}{\int_0^\infty I(\lambda)\,\mathrm{d}\lambda S(Q, w)\,\mathrm{d}w} \tag{13}$$

where λ is the neutron wavelength, w is the angular frequency and t is time. Such polarization changes can only be measured by dedicated instruments that can detect the neutron polarization state.

3 NEUTRON PRODUCTION AND MEASUREMENT

Although the method of neutron production may at first be of little importance to the experimentalist the energy, intensity and time structure of the neutrons are important factors affecting the measurements that can be performed. For this reason, a brief explanation of neutron production and measurement is included here. Regardless of the method of production, the current generation of neutron sources are all relatively weak. The most intense neutron sources provide beams with fluxes at the sample of 10^7 neutrons $\mathrm{cm}^{-2}\,\mathrm{s}^{-1}$ compared with a typical flux from a laboratory laser of 10^{15} photons $\mathrm{cm}^{-2}\,\mathrm{s}^{-1}$. This means that in order to make the most of these weak beams, care has to be given to optimize neutron transport from the source and to the construction of the instruments themselves.

Methods of neutron production are basically divided between nuclear reactors and spallation sources. Nuclear reactors for neutron production such as the ILL reactor at Grenoble, France, are not the same as power-generating reactors since these latter reactors are not designed to allow radiation to be emitted from the reactor core. In neutron production reactors, holes in the core container are essential to allow the neutron to be emitted. Within the reactor core, fission reactions often from enriched uranium (^{235}U) produce high-energy neutrons (1–2 MeV). These neutrons are too highly energetic for using in scattering experiments and are therefore passed through moderators most probably containing D_2O, H_2O or graphite, which cause the neutrons to be multiply scattered, losing energy with each collision. The emerging neutrons will therefore have energies dependent on the moderator temperature and described by a Maxwell–Boltzmann (MB) velocity distribution. For a water moderator at 50 °C this gives a peak flux with a wavelength of 1.4 Å. Owing to the nature of the fission

process, reactors produce a continuous source of neutrons as a function of time. Neutron flux is limited to a large extent by heating effects of the fission process within the reactor, since the maximum flux is produced as a balance of the heat dissipation needed within the core. Owing to the continuous nature of neutron production, one specific wavelength is chosen for a specific neutron spectrometer depending on the types of measurements required to be performed. Wavelength and energy selection is often achieved by velocity selecting rotating choppers or by reflection from a single plane of a crystal.

By contrast, spallation neutron production uses a beam of highly energetic particles such as protons which chip off neutrons from the heavy nuclei of the target material. The neutron yield produced per proton is fairly high with minimal heating effects, but is set against the extremely high cost of producing the protons. At the ISIS neutron spallation source at the Rutherford Appleton Laboratory, UK, 800-MeV protons are produced by combining a linear accelerator with a synchroton. The resulting protons and hence the neutrons are produced in short pulses with a peak flux which is larger than reactor sources. However, between each pulse the neutron flux falls to zero so the time-integrated average flux is less than for a reactor. As with reactors, the neutrons produced are highly energetic and have to be moderated. At the ISIS facility three types of moderator are used, H_2O at ambient temperatures, liquid methane and liquid hydrogen. The neutrons passing through the moderators are characterized by a wide MB velocity distribution giving a ''white'' beam of neutron wavelengths within each pulse. Velocity and hence wavelength determination in such white beams are determined by time-of-flight (TOF) methods. Here the time taken for the neutron to travel the known distances from the target–moderator assembly to the sample and detectors is measured, giving the velocity and through de Broglie's relationship the wavelength. Energy selection for white-beam instruments can be performed either before or after scattering from the sample and again depends on the spectrometer design and the information required.

To study the conformation, morphology and dynamics of polymeric systems, a wide range of both momentum and energy transfer must be covered. This is not possible with one spectrometer alone but requires dedicated instruments, each of which is optimized to solve specific structural or dynamic problems.

4 APPLICATIONS OF NEUTRONS TO POLYMERIC MATERIALS

The following discussion outlines some of the many uses that neutrons have been applied to for studying polymer systems. Although specific systems are mentioned in the text, this represents only a small number of those that have been studied. In order to supplement the information in the text, Tables 1–4 contain a more comprehensive listing of systems and references found in the literature, mostly within the last 20 years. Although the intention was to be as thorough as possible, these tables certainly do not contain all the references on polymer systems studied by neutrons, which would run to several thousand for the past two decades alone.

4.1 Effects of Deuteration

Although deuteration is widely used in neutron scattering, it does have an influence on the behavior of the polymer mixture. At higher concentrations of labeled polymer it was observed that for isotopic blends of deuterated and hydrogenous analogs of the same polymer phase separation occurs. This was first observed using SANS for PB,[34] PS[34] and PDMS.[35] Surface segregation has subsequently been observed using NR for isotopic blends in thin-films.[36,37] The segregation in these isotopic mixtures occurs due to a weakly unfavorable χ interaction parameter originating from the difference in the polarizability between the C−H and C−D bonds.[36] The effect is only observed if $\chi N > 2$ is satisfied, where N is the degree of polymerization. Since χ is typically very small for isotopic mixtures [χ for h-PS/d-PS is 2×10^{-4}[38]), N must be large before separation occurs.

High levels of labeling which can increase the signal intensity can lead to difficulties due to these isotopic effects. By working at low levels of deuteration it is possible effectively to remove the effects of labeling. Another possibility is to measure a number of samples with different deuteration levels and extrapolate to zero concentration of labeled polymer.

4.2 Determination of Molecular Parameters

As seen from the equations above, detailed analysis of the Q dependence of the SANS profiles provides information on the polymer chain conformation and also the interaction parameter. Using the Debye or RPA equations, the radius of gyration of the polymer can be calculated. This also applies to blends of polymers in the one-phase region where radii of gyration for each of the blend components can be obtained. Analysis of SANS from blends of PS and PVME[39] and PS and P*p*MS,[40] for instance, have used weighted average radii of gyration as fitting parameters of the data.

The radius of gyration has been studied as a function of blend composition and temperature. In a PMMA blend with SAN annealed at 140 °C, the average radius of gyration goes through a minima at an approximate 35%

volume fraction of PMMA.[41] Excess scattering was also observed and has been interpreted in terms of effective conformational changes of the PMMA due to the affect of rotational states on intermolecular interactions or compositional variation in the interaction parameter. Similar composition and temperature dependence has also been observed in other blends such as PS–isotactic(*i*)-PVME deriving from *i*-PVME self-correlations.[42]

Isotopic polymer mixtures have proved to be ideal model systems for exploring the limitations of the widely used Flory–Huggins theory and for testing and improving new theories of polymer thermodynamics. These isotopic blends lack the structural asymmetries and specific interactions encountered in blends of chemically distinct species. The Flory–Huggins interaction parameter, χ, between deuterium-labeled and unlabeled segments of the same species should in principle be independent of concentration (ϕ), but SANS experiments have shown that it exhibits a minimum at $\phi \approx 0.5$ for PVE, PEE[43] and PE.[44] By comparison, isotopic mixtures of PS show a maximum in χ as shown in Figure 5.[44]

Some blends have demonstrated a χ dependence on not only composition but also molecular weight as seen from the SANS obtained from PS/PVME[39] and PEO/PMMA.[45] The origin of this composition dependence is still unclear but may be due to volume changes on mixing and concentration fluctuations.[46–48]

Blend miscibility can be affected dramatically under the influence of pressure, for instance upward shifts of 25–30 °C kbar^{-1} of the spinodal have been observed for PS/PVME blends.[49] Typically the pressure dependence of the χ parameter is determined, and separated into a pressure-independent enthalpic contribution and an entropic component which decreases with increasing pressure. Such interpretations have been applied to SANS data obtained from blends of PS/PVME and PS/PPMS which exhibit lower and upper critical solution temperatures, respectively.[50,51] Pressure has also been shown to have an effect on the chain dimensions, where an increase in pressure results in a reduction in chain dimensions.[49,52,53]

Figure 5 Plot of Flory–Huggins interaction parameter versus volume fraction of d-PS in a blend with h-PS calculated from SANS data taken at 160 °C. The degree of polymerization of d-PS is 11 500 and that of h-PS is 8700 (solid circles) and 15 400 (open circles). The dotted lines represent error limits on the interaction parameter due to systematic error in degree of polymerization and absolute intensity. (Reproduced by permission from Londono et al.[44])

The study of short-range order in disordered polymers is particularly challenging owing to both the structural complexity and absence of periodic lattices in these materials. The complexities arise from the variety of both intra- and interchain correlations. WANS has been used to obtain quantitative information on the nature of the chain segments, in terms of local chain conformation and chemical configuration, and on the spatial and orientational correlations of segments.[12,54,55]

WANS experiments on *a*-PS have shown that true quantitative neutron scattering data to be obtained over a large scattering vector range for hydrogenous polymers. Results for samples of both fully protonated PS in comparison with its deuterated analog have shown that investigating the local structure of hydrogenous polymers provides detailed information about the polymer without the need for deuteration, making it an important tool for commercial systems.[12] Despite this, isotopic substitution is an important tool for such studies. The cation environment in molten lithium iodide-doped PEO has been studied using SANS utilizing ^{6}Li and deuterated PEO.[56] The experimental results of these studies have been confirmed using molecular dynamic simulations and show that the Li^+ has a coordination number with oxygen of 3.5, and changes of the coordination with variations in Li–O bond length have been mapped.

4.3 Phase-separated Systems

The scattering behavior from a two-phase blend is distinctly different from that observed when the system is in the one-phase regime. As with LS, this distinction provides a means of locating the phase boundary. The phase separation process can also be followed and because the scattering behavior is different for the nucleation and growth and spinodal decomposition mechanisms, it is therefore possible to easily distinguish between the two. The phase separation process in polymers is slow enough that time-resolved scattering experiments can be performed. In the very early stages of spinodal decomposition the development of regular co-continuous

structures give rise to a maximum in the scattering pattern. The maximum occurs at a specific Q value (Q_m) which is indicative of a preferred length scale in the phase separated morphology, given by $\Lambda_m = 2\pi/Q_m$. Initially the characteristic size of the fluctuations remains constant despite the increasing difference between the two phase compositions, and therefore the position of the characteristic spinodal peak at these early times remains constant.[57–60] At longer times the position of Q_m moves to lower Q,[61] resulting in morphology which becomes indistinguishable from that developed during nucleation and growth. Nucleation and growth mechanisms do not produce morphologies with regular structure and thus lack a maximum as seen for spinodal decomposition. The phase separation is, however, characterized by a significant increase in scattering, and is analogous to the cloud point observed in LS. Owing to the differences in domain sizes measured by LS and SANS the onset of these cloud points may differ.

In general, the use of SANS to study two-phase morphology is not the technique of choice, since other more available techniques can provide the information required. However, in a number of cases the use of neutrons is the only way of obtaining the information. Such cases arise, for example, when the samples are too thick or opaque for other scattering methods or when no contrast can be obtained other than by deuteration, as may be experienced for polyolefin blends.[62–64] SANS has been widely applied to studies of polymer micelles and also block copolymer morphology.

The morphology of block copolymers has been investigated extensively both in the bulk and in concentrated solutions. If the blocks of the copolymer are incompatible microphase separation may occur leading to phases with spherical, cylindrical, gyroid or lamellar morphology depending on the block lengths and matrix. For instance, the morphology of a range of PS/PB diblock copolymers has been investigated which show well-resolved Bragg peaks originating from a macrolattice of body-centered cubic packing (BCC) of PB spheres.[65,66] Studies of PS-block-PI (PS-*b*-PI) using SANS has also shown spherical,[67] lamellar and cylindrical morphologies (see Figure 6).[68,69] Lamellar domain spacings of copolymer blends with their homopolymers and conformations of block chains in their microdomains have been studied for PS and PVP homopolymers and copolymer.[70] SANS studies of PE/PEP diblock copolymers blended with PE and PEP homopolymers have also been used to test theories where melt behavior is controlled by a common interaction parameter.[71]

4.4 Shear and Deformation

By using large-area detectors, SANS instruments are able to observe any deviation from isotropic scattering,

Figure 6 SANS profile of a styrene–isoprene block copolymer with $M_n = 178\,100$ and polydispersity 1.06. The weight fraction of styrene is 0.73. The interdomain distance obtained from the position of the first Bragg peak maxima is 95.2 nm. (Reproduced by permission from Richards and Thomason.[67])

as may be experienced by systems with defined order, or preferred orientation, from either single chains or particulates. In this respect, SANS has been used to study deformation and relaxation processes of polymer chains.[72–76] The scattering in these oriented polymer systems now displays an anisotropic scattering pattern which is typically ellipsoidal in shape, although other shapes have been observed. Relative to the extension or shear propagation axis, the radius of gyration can then be analyzed with respect to these orthogonal directions.

There is considerable interest in the behavior of polymer solutions under shear and SANS has been applied to help interpret the morphological changes that occur under such external force fields.[77] The high penetrability of the neutron makes in situ rheological measurements possible in any required geometry, including Couette,[78,79] parallel plate[80] and Poiseuille.[81,82] Chain deformation by the shear flow creates changes in the polymer chain conformation, which can be observed, by changes in the scattering intensity parallel and perpendicular to the flow creating anisotropic scattering. Polymeric micelles formed by copolymers at high concentrations can form high degrees of ordering such as BCC or face-centered cubic (FCC) polycrystalline structures.[79,80] The steady-state ordering behavior can be disrupted by application of shear such as observed for PS-*b*-PI copolymers in decane where the FCC structure shows a transition to (111) sliding layers. As the shear rate is increased these (111) planes

are oriented normal to the shear gradient. In contrast the BCC polycrystals form (110) layers normal to the shear gradient.[79] Similar long-range ordering has also been observed for diblock copolymers of poly(styrene-*b*-ethylene-*co*-propylene) in the selective solvent dodecane at concentrations above 3 wt%, where the shear rate affects the lattice ordering.[83] Another method of alignment is in magnetic fields and a number of studies have shown anisotropic scattering of LCPs. For example, a main-chain semiflexible copolyester has been shown to align using a magnetic field of 0.6 T in the nematic phase between 160 and 250 °C.[84,85] Using SANS, the chain anisotropy, radius of gyration, average degree of polymerization and persistence length of these oriented polymers have been obtained.

Not all scattering from oriented polymers is so straightforward and unusual anisotropic scattering such as figure of eight "butterfly" patterns has been observed for uniaxial extension of polymer networks or swollen gels.[73,75,76,86] This anomalous scattering behavior has been studied using deuteration contrast variation methods and indicate that the butterfly scattering patterns from rubbers originate from the interchain structure factor. This implies that there are spatial concentration fluctuations in labeled free chains on length scales that are larger than the characteristic mesh size of the system. This contradicts the classical hypothesis of molecular rubbers and has led to the postulation of the cross-linking process introducing random large-scale spatial fluctuations in elastic modulus, so-called hard and soft zones. The butterfly patterns would then result from anisotropic spatial separation of the hard zones, which would amplify concentration fluctuations in the stretching direction.[87,88] In gels and swollen networks, theories based on thermodynamic and frozen concentration fluctuations have been suggested to explain the appearance of butterfly patterns.[89,90] These theories have been critically tested by analyzing the butterfly patterns obtained by randomly cross-linked PS gels swollen by deuterated toluene.[86]

In recent work, McLeish et al. used SANS to help understand the rheological behavior of PI with H-shaped architecture,[91] which can expect to show an intriguing combination of features of star and linear polymers. H-polymers have four star-like arms which must relax by linear pathlength fluctuations, but are connected by a "cross-bar" which cannot move at all in the entangled state. Until the dangling arms retract to their branch points the crossbar cannot move and then motion occurs in the same way that star polymers diffuse. By measuring the anisotropic scattering (see Figure 7), and therefore morphology obtained from stretched and instantly quenched samples of carefully deuterated H-shaped PIs, the theories relating to their retraction dynamics have been studied.[91]

Figure 7 SANS pattern from an H-shaped polymer taken after a extensional stretch of 2.3. The direction of stretch is in the vertical direction. A pronounced asymmetry is observed consistent with theoretical calculations. (Reproduced by permission from McLeish et al.[91])

4.5 Homopolymer Interfaces

Many homopolymer systems are characterized by narrow interfacial widths owing to the nature of their immiscibility. The width of these interfaces can be described in terms of self-consistent mean-field theories and is simply determined by the Flory–Huggins interaction parameter, χ, and defined in Equation (14):[92]

$$w_\infty = \frac{2a}{\sqrt{6\chi}} \tag{14}$$

where a is an average segment length of the two polymers and the ∞ symbol indicates that this equation strictly applies only to infinite molecular weights. A common immiscible polymer pair of PMMA and PS with a χ of 6×10^{-2}[93] gives $w = 2.6$ nm. With its exceptional spatial resolution, NR is ideally suited to studying surfaces and interfaces on such length scales and has been widely used for such studies.[94–99] The shape of the interfacial width as described by theory to be a hyperbolic tangent function has been confirmed using NR.[100] Early NR measurement of these immiscible homopolymer systems always obtained interfacial widths larger than that predicted by theory.[94,95] This discrepancy can be accounted for by considering perpendicular fluctuations to the interface. The apparent broadening observed by NR can be attributed to thermally induced capillary waves.[96,99,101,102] The measured interfacial width w is simply given by the quadrature addition of the capillary wave amplitude and the theoretical width, so that

$w = (w_0^2 + w_c^2)^{1/2}$, where w_0 is the intrinsic (unbroadened by capillary waves) interfacial width as predicted by theory and w_c is the capillary wave amplitude. The capillary wave component of the interfacial width can be defined as in Equation (15):[99]

$$w_c^2 = \frac{k_B T}{2\gamma_0} \ln \frac{(2\pi/\Delta_0)^2}{(2\pi/\lambda_c)^2 + (2\pi/a_d)^2} \qquad (15)$$

where $\Delta_0 = w_c/\sqrt{2\pi}$. The capillary wave broadening is therefore dependent on the in-plane coherence length of the neutron, $\lambda_c \approx 20\,\mu m$, the dispersive capillary length, $a_d = 4\pi\gamma_0 d^4 A^{-1}$ (d is the layer thickness), the Hamaker constant, A, and the interfacial tension $\gamma_0 = av^{-1}k_B T\sqrt{\chi/6}$ (v is the monomer volume). As can be seen from Equation (15), determination of the interfacial width using NR is therefore a route to determining the Flory–Huggins interaction parameter, χ, and γ_0.

This approach to determining interfacial parameters has been applied to a number of homopolymer systems: PS/PMMA,[94,95] PS/PBrS,[96,97] and PS/P*n*BMA.[98,103] Most studies have been carried out at room temperature on samples that have been annealed to equilibrium at temperatures above the glass transition temperature, T_g, and rapidly quenched. The interfacial properties at equilibrium are therefore assumed to be trapped and immobile at the room temperature. This approach does not allow investigation of crystalline polymers where the macroscopic roughness associated with the crystallinity prevents room temperature measurements.[104] By using a heated cell which confines the polymer films it has been possible to measure crystalline film interfaces in situ at elevated temperatures. A number of such systems have been studied using various grades and tacticities of PE, and PP, PMMA and PS.[104–106] For blends of PE and PP the interfacial width is seen to be larger for those containing (*a*-PP) in comparison with to its *i* form (*i*-PP).

Polymer adsorbed layers are widely used for many applications, such as viscosity modifiers and dispersion stabilizers in colloidal dispersions.[107] SANS has been used to study the surface-adsorbed polymers on spherical polymer lattices, inorganic oxide particles or emulsion droplets, whilst NR utilizes flat surfaces.[108–110] These techniques are able to provide the component volume fraction profiles at the interface and the amount of adsorbed polymer. This requires careful design of the experiment since meaningful interpretation from SANS data is only possible if the scattering is from simple geometries, with minimal interlayer interactions, excluded volume effects and multiple scattering effects. If the layers become too extended into the melt or solution then NR will also not be able to distinguish the polymer from the matrix and the volume fraction profile in these tail regions.

4.6 Polymer Interdiffusion

The observation of the dynamics of the interdiffusion process is ideally suited to investigation by NR, where it is possible to resolve the early stages where only chain segments move across the initially sharp interface.[103,111–120] At times smaller than the reptation time of the molecule, several time dependences predicted by theory have been observed using NR (see Figure 8).[111] Only after the interface has become sufficiently large, comparable to the polymer chain dimensions, does it achieve essentially bulk toughness.[121]

Using multiple alternating layers of PS and d-PS, the effect of chain confinement has been observed when the layer thicknesses are on length scales approaching or below the overall dimensions of the polymer.[122] The multilayer composition creates Bragg peaks in the reflectivity profile which disappear with interdiffusion of the layers. The change in the composition profile is seen to be diffusive even for times less than the reptation time, with a Q-dependent diffusion coefficient that decreases with increasing Q. Related work on this system studying the effects of confined geometry and substrate interaction on the short-time interdiffusion in polymer films has also been studied. Only a slowing of interdiffusion dynamics for thin films sandwiched between two thicker ones is detected as well as a still smaller interdiffusion for thin films placed directly on the substrate, which is attributed to polymer–substrate interaction.[123]

An alternative approach to measuring diffusion using neutrons is, of course, with SANS. One such example is the diffusion observed in miniemulsified lattices of PS and d-PS.[124] Samples containing a small fraction of

Figure 8 Interfacial width (root-mean-square half-width) between h-PS and d-PS as a function of reduced time at a reference temperature of 120 °C. The arrows indicate the times corresponding to the Rouse entanglement (τ_e), Rouse relaxation (τ_R) and reptation (τ_r) times. (Reproduced by permission from Karim et al.[111])

deuterated particles were annealed well above T_g and the average depth of penetration of the deuterated chains in the protonated matrix was measured during the annealing process.

4.7 Copolymers at Interfaces

Reflectivity studies have contributed greatly to the understanding of the behavior of copolymers at homopolymer interfaces.[125,126] Studies using NR have shown that it is possible to determine quantitatively the amount of copolymer segregated to the interface and also the distribution of copolymer segments at the interface. By extensive use of deuterium labeling, the precise distribution of a PS-*b*-PMMA diblock copolymer at the interface between PS and PMMA homopolymers has been determined.[125] The width of the PS/PMMA interface including the copolymer is 25% larger than that of the bare interface in the absence of copolymer, indicating a significant overlap of the homopolymers.

When the interface between two homopolymers becomes diffuse, such as is the case when a compatibilizing copolymer is added to the mixture, SANS data can no longer be analyzed by the Porod law described above. Boundaries of finite width can be incorporated by convolution of a smoothing function[127,128] expressed in terms of the Fourier transform function, $H^2(Q)$, which is related to the density profile across the interface, allowing the determination of the interface thickness, d_I. A relatively good approximation for this Fourier transform function is a Gaussian distribution.[129] The Porod scattering from a two-phase blend with diffuse interfaces is given by $I(Q) = P(Q)H^2(Q)$ with the analytical expression for $P(Q)$ varying depending on the phase morphology.[130] The scattering from this type of system can therefore be expressed by Equation (16).[130]

$$\ln[I(Q)Q^{\eta}] = \ln \kappa_m - \sigma_d^2 Q^2 \qquad (16)$$

where κ_m is a parameter describing the morphology of the particle shapes according to the value of η, which takes a value of 4 for spherical, 3 for cylindrical and 2 for lamellar morphology. The interface thickness, d_I, can be determined from the second moment of the density variation, o_d^2, from the relationship $d_I = \sqrt{12\sigma_d}$.[130]

This method of analysis has been applied to blends of PS and PMMA compatibilized with the deuterated low molecular weight diblock copolymer d(PS-*b*-PMMA), where Porod scattering indicates that lamellar structures are present ($\eta = 2$).[131] This behavior can be understood in terms of the interface curvature and packing requirements of the copolymer. The interface thickness as a function of copolymer volume fraction is shown in Figure 9. These values of d_I can be compared with the theoretical predictions of Helfand and Wasserman.[132–135]

Figure 9 Interphase thickness width between PS and d-PMMA in a blend as a function of concentration of diblock copolymer of PS-*b*-PMMA, obtained from fits to a modified Porod plot of SANS data. (Reproduced by permission from Bucknall.[131])

In thin-films, the microdomain morphology of diblock copolymers is greatly influenced by the interactions with the surfaces. NR studies have been able to provide detailed understanding of these systems. Oscillatory concentration depth profiles are expected to be observed perpendicular to the surface owing to the segregation of the chemically distinct but molecularly connected segments of the copolymer. Such ordering has been observed when diblock copolymer films are on silicon,[95,136–139] or confined between solid walls.[140–142] The lamellar ordering is due to the preferential segregation of one of the blocks to the surface. These lamellae have been shown using NR to have a very regular structure provided that the film is not so thick as to allow disorder to be introduced into the bulk of the film.[138] If the total film thickness is not a multiple of the lamellar period then frustration can result in island formation at the free surface.[140,143] In films which are confined between solid surfaces, this frustration cannot be removed by island formation. Under these circumstances, the frustration is distributed throughout the sample by slight increases in the lamellar period, and as the total thickness increases there is a point at which the frustration, rather than distributing throughout the film, creates another lamellar layer. If the lamellar thickness is plotted against the total film thickness, a series of discrete steps is observed (see Figure 10).[144]

4.8 Polymer Dynamics

The information obtainable by INS and QENS overlaps considerably with other experimental techniques, in particular NMR,[145] IR and Raman spectroscopy, photon correlation spectroscopy and dielectric measurements.

Figure 10 Number of periods confined between two solid surfaces, t/L, for a d-PS-*b*-h-PMMA copolymer, as a function of reduced film thickness, t/L_0. (Reproduced by permission from Russell.[144])

This has meant that INS and QENS have not achieved the widespread application to polymers as perhaps SANS and NR have enjoyed. However, in certain circumstances neutrons provide distinct advantages over other techniques which have necessitated their use, such as lack of selection rules governing the observable motions and contrast enhancement with deuteration schemes. In addition, the technique inherently conveys direct information about both spatial and dynamic information, which cannot be obtained by other techniques and can be used to discriminate between inter- and intramolecular effects. Reviews of applications to polymers have been published.[11,146]

Even in the solid state, polymer chains are very mobile, and as a consequence analysis of their dynamics relies on decoupling the various kinds on motion that the chains may undergo. By assuming that the timescales over which these motions occur are very different, it is possible to separate translations, vibrations and rotations. The total scattering law is then a convolution of the respective translational, vibrational and rotational laws. These can be separated experimentally by choosing the appropriate energy and time domains to observe the motion required. In general, translational motion broadens the whole of the elastic peak, while rotation gives a sharp elastic peak with a broadened foot. Vibrational motion, on the other hand, gives sharp peaks either side of the elastic peak that are analogous to the Stokes and anti-Stokes lines observed in Raman spectroscopy. Experimentally, many inelastic translations may be observed corresponding to the many vibrational modes in the sample.[11]

The observed inelastic and quasielastic scattering behavior are characteristic of the polymer.[11] The INS from the crystalline polymer PTFE shows an intense unbroadened elastic peak and well-defined inelastic structure that varies strongly with scattering angle and is due to phonons within the crystalline regions. By contrast, for an amorphous polymer such as PMMA, the inelastic phonon scattering is much less apparent with only a broad inelastic peak, characteristic of molecular vibration. In this case this has been attributed to torsional motion of the α-methyl group. A slight broadening of the elastic peak (quasielastic broadening) at its base is also observed deriving from molecular rotations and can be assigned to deriving from the ester methyl group. An INS spectrum of PDMS rubber shows strong inelastic scattering which is Q dependent arising from the methyl group torsional mode. Quasielastic broadening is also present and is due to a main-chain ''wriggling'' motion which is characteristic of rubbery state polymers.

To date only a limited number of studies have been reported on dynamic studies on polymer blends. Blends of selectively deuterated PMMA (d_5-PMMA) and SCPE and d-PS/PVME have been studied in detail to investigate the effect of blending on the local motions below T_g.[147,148] Measurements on these systems have been performed on these blends to investigate the effect blending has on the rotational motion of the ester methyl group in PMMA and the OCH_3 moiety in PVME. In the d_5-PMMA/SCPE blend the scattering from the SCPE is purely elastic owing to the absence of side-groups. The d_5-PMMA contributes to both the elastic and quasielastic components, where the latter is described by rotational hopping of the CH_3 groups over the threefold potential barrier.[147–149] The quasielastic broadening, which can be simply modeled by a Lorentzian function convoluted with the instrumental resolution, is considerably reduced in the blend compared with pure PMMA. The activation energy that characterizes the motion of the CH_3 increases with increasing SCPE content, indicating that the rotational motion is hindered in by the SCPE. By comparison for the d-PS/PVME system the presence of the d-PS had no effect on the rotational motion on the OCH_3 group.[148]

NSE has been used to check the validity of the reptation model at the molecular level, since it is able to observe individual molecules in crowded surroundings. Using this technique, many studies have been made to understand polymer reptation.[5,6] Using blends of poly(tetrahydrofuran) (PTHF) of high and low molecular weight, the effects of chain entanglements were investigated. Two samples were studied, where high molecular weight PTHF was blended in a matrix of either low or high molecular weight deuterated PTHF. Since the matrix

polymer was deuterated it is possible to measure the intermediate structure factor $S(Q,t)$, which derives from the Fourier transform of $S(Q,w)$. The NSE data for the low molecular weight matrix could be explained using simple Rouse-type behavior, but could not be used to explain the data for the high molecular weight matrix sample. Using a reptation model these data could be explained and gave a tube diameter, D_r, for the reptating polymer of 3.0 nm. Improvements in instrumental resolution of the spin-echo instruments will allow more detailed analysis of reptation theory to be tested.

The use of inelastic scattering has been pursued for investigations into the motion responsible for the α-relaxation process associated with the glass transition temperature. Among other techniques applied to these studies, incoherent QENS may be able to provide insights into the local motions of this α-relaxation process. Using simple polymers such as PB, main-chain motions such as conformational transitions have been shown to occur alongside cooperative motion.[150,151] Recently, the mode coupling theory of glass transition has attracted the attention of neutron scatterers since the predicted singularity in the density fluctuations can be measured directly by incoherent QENS. The divergence observed in the vibrational amplitudes of the Debye–Waller factors are as predicted by the mode coupling theory, although a number of questions remain open as to the validity of the model for all glassy polymers.

INS has also been applied to the study of microphase separation in ionomers of PS.[152] The differences in *a* and *i*-PS in comparison with sodium sulfonated PS (Na SPS) were observed and vibrational modes due to ring and chain moieties identified by selective deuteration. A typical set of INS spectra for these polymers is shown in Figure 11. Sulfonation was shown to have an effect upon the spectrum of *i*-PS very similar to that observed with *a*-PS. Observation of a new mode at low wavenumbers indicates that the process of sulfonation results in a release of a low-frequency ''breathing mode'' between the chains. Detailed studies of both randomly oriented and stretched PE have been used to understand the crystallization behavior and to test quantitative spectra calculations using ab initio methods.[153,154]

5 CONCLUSIONS

Since the 1950s when neutrons were first applied to condensed matter physics, there has been an enormous growth in publications where neutrons have been applied to experimental studies. This overview has only been able to give a flavor of the huge amount of published literature available on polymer studies with neutrons, and it is hoped that it is clear that in many ways the neutron is the ideal probe for studying polymers. Combined with the use of deuteration, neutron scattering has provided information about both structure and dynamics not obtainable by other techniques.

The development of improved instruments at existing neutron sources means that the application of neutrons to answer the many problems of polymer science has a positive future. However, with the possibility of the next generation of neutron sources that are at present either planned or under construction, another explosion of interest in neutrons is anticipated. These new sources, with the potential for much higher fluxes, will make possible a whole host of experiments that have been waiting for such advances. Indeed, there are bound to be many experiments performed on these new sources which have not yet even been conceived. Of the large number of significant advantages such high flux sources will provide, the possibilities of smaller sample volumes, better resolution and even true time-dependent studies are exciting prospects for the future.

ABBREVIATIONS AND ACRONYMS

a	Atactic
BCC	Body-centered Cubic Packing
BPA	Bisphenol A
EF	End Functionalized
EPDM	Ethylene–Propylene–Diene Rubber
FCC	Face-centered Cubic
i	Isotactic
INS	Inelastic Neutron Scattering
IR	Infrared
LCP	Liquid Crystal Polymer
LS	Light Scattering

MB	Maxwell–Boltzmann
*m*PA	Poly(*N*,*N*′-dimethylethylene sebacamide)
NMR	Nuclear Magnetic Resonance
NR	Neutron Reflection
NSE	Neutron Spin-echo
ODT	Order–Disorder Transition
Pα-MS	Poly(α-methylstyrene)
PA	Polyacrylate
PAEK	Poly(aryl ether ketone)
PAl	Polyalkane
PAn	Polyaniline
PAS	Poly(aryl sulfone)
PAT	Polyalkylthiophene
PB	1,4-Polybutadiene
PBA	Poly(butyl acrylate)
PBMA	Poly(butyl methylacrylate)
PBrS	Polybromostyrene
PBTP	Polybithiophene
PC	Polycarbonate
PCHA	Poly(cyclohexyl acrylate)
PCL	Poly(ε-caprolactone)
PCP	Polychloroprene
PDMS	Polydimethylsiloxane
PDPO	Poly(dimethylphenylene oxide)
PE	Polyethylene
PEA	Poly(ethyl acrylate)
PEB	Polyethylbutene
PECH	Polyepichlorohydrin
PEE	Poly(ethylethylene)
PEEK	Poly(ethyl ether ketone)
PEG	Poly(ethylene glycol)
PEI	Poly(ether imide)
PEK	Poly(ethyl ketone)
PEO	Poly(ethylene oxide)
PEP	Polyethylpropylene
PEs	Polyester
PET	Poly(ethylene terephthalate)
PI	Polyisoprene
PIB	Polyisobutene
PMB	Polymethylbutene
PMMA	Poly(methyl methacrylate)
P*n*BMA	Poly(*n*-butyl methacrylate)
PP	Polypropylene
PPh	Polyphenylene
PPl	Polyphenol
PPMS	Polyphenylmethylsiloxane
P*p*MS	Poly(*p*-methylstyrene)
PPO	Poly(phenyl oxide)
PPV	Polyphenylenevinylene
PPy	Polypyrrole
PS	Polystyrene
PSO	Polysiloxane
PSVP	Poly(styrene–vinylpyridine)
PTFE	Polytetrafluoroethylene
PTHF	Poly(tetrahydrofuran)
PU	Polyurethane
PVA	Poly(vinyl acetate)
PVC	Poly(vinyl chloride)
PVE	Polyvinylethylene
PVME	Poly(vinyl methyl ether)
PVP	Polyvinylpyridine
PVPh	Polyvinylphenol
QENS	Quasielastic Neutron Scattering
RPA	Random Phase Approximation
SAN	Poly(styrene–acrylonitrile)
SANS	Small-angle Neutron Scattering
SAXS	Small-angle X-ray Scattering
SBR	Styrene–Butadiene Rubber
SBS	Styrene–Butadiene–Styrene Copolymer
SCPE	Solution-chlorinated Polyethylene
SPS	Sulfonated Polystyrene
TOF	Time-of-flight
WANS	Wide-angle Neutron Scattering

Nuclear magnetic resonance (NMR) imaging is a noninvasive technique which is based on the phenomenon of NMR. The resonance frequencies of the nuclear spins can be made spatially dependent by introducing a magnetic field gradient into the NMR experiment. The acquired NMR signal is thus spatially encoded and a spin-density image of the sample can be reconstructed.

While originally developed for medical applications, NMR imaging is now increasingly applied for materials investigations. The main advantages of the technique are its nondestructivity, which allows processes to be investigated in situ, and the possibility of introducing NMR spectroscopic information and relaxation contrast into the NMR images. Limitations, on the other hand, are the relatively low sensitivity and the broad NMR lines of polymers, both of which limit the spatial resolution. Whereas the latter can be dealt with by suitable methods, the sensitivity ultimately restricts the achievable spatial resolution of conventional NMR imaging techniques to about 10 μm^3. NMR imaging therefore must not be considered as a competitor of other microscopic techniques such as electron microscopy but as a characterization technique that provides supplementary information. Examples illustrating all these aspects are given in this article.

1 INTRODUCTION

Since its discovery 50 years ago, NMR spectroscopy has undergone successful development, resulting in a wealth of applications in various research fields, including chemistry, medicine and material science. One of the most intriguing developments in this field is NMR imaging which has evolved from early test experiments on phantom samples to its present importance as an indispensable tool for medical diagnosis. Its importance derives from several advantages which for many investigations make it superior to other diagnostic techniques. NMR imaging is sensitive to soft tissue and gives an insight into the human body in a completely noninvasive way. Moreover, as a unique advantage, NMR contrast parameters that specifically reflect particular tissue differences can be introduced. A wealth of methods has been developed on this basis, making NMR imaging a rapidly growing field.

In material science, useful applications of NMR imaging have been shown only during the last few years, although the potential of this technique was recognized early. For a long time progress was hampered by the broad NMR lines of materials. Broad lines result in a degradation of the spatial resolution and in case of rigid polymers in a complete failure of conventional NMR imaging techniques. Moreover, the ultimately achievable resolution of around 10 μm^3 is not competitive with that of other microscopy techniques such as light or electron microscopy. As will be presented below, however, such high spatial resolution is not required for many interesting applications in polymer science while the nondestructivity, flexibility and spectroscopic selectivity of NMR imaging are indispensable advantages. Strong efforts have therefore been made to overcome the

technical and methodological problems of NMR imaging in materials, resulting in a rapid growth of methods and applications in science and in industry.

It is the main intention of this article to give an overview of the methods and possibilities of NMR imaging for polymer characterization, concentrating on some representative examples. Supplementary details can be found in books[1–5] and in earlier reviews on imaging of solids,[6–8] rubbers and other materials.[9–15]

The article is divided into six sections. Section 2 gives an introduction to NMR imaging and discusses the problems and possibilities of its application to materials. The section is divided into sub-sections so that the reader might skip those parts with which he/she is already familiar. Section 3 then discusses applications to soft materials for which standard NMR imaging techniques can be used. Imaging of rigid polymers, which is technically and methodologically more demanding, is described in section 4. The various methodological approaches are briefly reviewed before applications are presented. Section 5 provides a brief overview of techniques which at present must be considered as being somewhat "exotic" but nevertheless show promise for the future. The article concludes with a summary in section 6.

2 PRINCIPLES OF NUCLEAR MAGNETIC RESONANCE IMAGING IN MATERIALS

This section provides the necessary background for the discussion of the imaging techniques and applications in the following sections. Readers without NMR knowledge are nevertheless advised to consult additional literature.[3–5]

2.1 Nuclear Magnetic Resonance Spectroscopy

2.1.1 Basics of Nuclear Magnetic Resonance

NMR is possible for nuclei with a non-vanishing nuclear spin. The most interesting nuclei with respect to NMR imaging of polymers are spin-1/2 nuclei such as protons (^{1}H). For these nuclei there are two possible states in a magnetic field, one with spin-operator component I_z parallel and the other with I_z antiparallel to the static magnetic field direction which by convention is chosen in the z-direction. Whereas the I_z components of the spins are well defined, the transverse components are not and in a semiclassical picture the spins can be considered to precess around the magnetic field $\boldsymbol{B}_0$ with a characteristic resonance frequency, the Larmor frequency [Equation 1]:

$$w_0 = -\gamma|\boldsymbol{B}_0| \tag{1}$$

where γ is the magneto-gyric ratio of the nucleus.

The two states have different energies, and in thermal equilibrium there is a surplus of spins with I_z parallel to the magnetic field so that a net magnetization in the z-direction results. Transitions between the two energy levels are excited by radiofrequency (rf) pulses of the resonance frequency w_0. Since NMR spectroscopy is a coherent technique, a description in terms of energy levels is not sufficient. For most NMR imaging experiments, however, the coherent nature can be taken into account by a simple magnetization-vector picture where the pulses act on the net magnetization $\boldsymbol{M}$ (see Figure 1a and b). The effect of the rf pulses on the magnetization vector is most conveniently described in a new reference frame (x', y', $z = z'$), the so-called rotating frame, which rotates with the angular frequency w_0 around the magnetic-field direction (see Figure 1a). Relative to this frame, the rf field $\boldsymbol{B}_1$ can be considered to be static, pointing for instance, in the $-y'$ direction. It causes the magnetization to precess around its direction analogous to the precession about $\boldsymbol{B}_0$ in the static (laboratory) reference frame. At the end of the rf pulse, the magnetization therefore is tilted with respect to the z-axis by an angle $\theta = -\gamma|\boldsymbol{B}_1|t$, where t is the duration of the pulse. An important flip angle for all NMR experiments is 90° where the magnetization is flipped into the plane transverse to the magnetic field $\boldsymbol{B}_0$. For instance, after a 90° pulse with phase $-y'$ the magnetization vector points in the x' direction of the rotating frame (see Figure 1a). Viewed from the laboratory frame, however, the magnetization is rotating with a frequency w_0 around $\boldsymbol{B}_0$ (Figure 1b). In a coil fixed in the x direction of the laboratory frame, therefore, the magnetic flux varies periodically and a voltage is induced as a function of time which is detected as the NMR signal (Figure 1c). It decays because of relaxation effects (see below) and is called free induction decay (FID). As will be discussed below, the FID contains all of the spectroscopic information, and the NMR spectrum (intensity as a function of frequency) is obtained from it by simple Fourier transformation.

2.1.2 Relaxation

Two main relaxation mechanisms are responsible for the decay of the signal:

- *Longitudinal relaxation (T_1)* describes the re-establishment of the equilibrium magnetization in the z direction after a certain time. The transverse magnetization, on the other hand, is reduced by this process. The energy is dissipated to the so-called lattice, i.e. to degrees of freedom outside of the spin system. In Figure 1(d), the build-up of the z magnetization by longitudinal relaxation is represented by the component $\boldsymbol{M}_z$.

Figure 1 Sketch illustrating the detection of the NMR signal. (a) The net nuclear magnetization $\boldsymbol{M}$ is aligned along the magnetic-field direction $\boldsymbol{B}_0$ (z direction). A resonant rf field is applied perpendicular to it. In a frame rotating with resonance frequency w_0 around $\boldsymbol{B}_0$, this rf field can be represented by a static vector $\boldsymbol{B}_1$ aligned, for instance, along the $-y'$ direction. The magnetization $\boldsymbol{M}$ precesses around $\boldsymbol{B}_1$ in the rotating frame as indicated. For a 90° excitation pulse, $\boldsymbol{B}_1$ is switched off as soon as $\boldsymbol{M}$ is aligned along the x' direction. (b) Viewed from the static frame, the magnetization precesses with frequency w_0 around $\boldsymbol{B}_0$ and thus induces a voltage $U(t)$ in the coil surrounding the sample. (c) The induced voltage as a function of time represents the NMR signal, the free induction decay (FID). The amplitude of the FID is proportional to the nuclear magnetization and the modulation represents the resonance frequencies of the detected nuclei. Fourier transformation provides the NMR spectrum. (d) The signal decay is caused by the loss of coherence (dephasing of the single magnetization vectors) due to field inhomogeneities and spin interactions. Also, the relaxation of the magnetization back to the z direction contributes to some extent to the decay.

- *Transverse relaxation (T_2^*)* describes the loss of phase coherence in the transverse plane (see Figure 1d, components $\boldsymbol{M}_t$). The dephasing results from the distribution of Larmor frequencies due to $\boldsymbol{B}_0$ inhomogeneities and from interactions between spins. It leads to a decrease in the acquired signal because the change of the magnetic flux through the coil is reduced.

In general (and particularly in solid materials), T_2^* relaxation is faster than T_1 relaxation and therefore dominates the FID. Thus, for NMR imaging experiments, longitudinal relaxation is important mainly because the time required for the re-establishment of the z magnetization determines the repetition time of the experiment.

2.1.3 Spin Interactions

As already stated, there are two mechanisms responsible for the loss of phase coherence, magnetic-field inhomogneities and internal spin interactions. The latter dominate in solid-state NMR whereas in liquids the large anisotropic part of the spin interactions is averaged out by fast thermal motions of the molecules and therefore does not contribute much to T_2^* relaxation. The FID of liquids thus is comparatively long. Fourier transformation leads to spectra with narrow lines while in solids broad and often featureless lines are found.

The spin interactions which are important with respect to materials imaging are outlined below.

Chemical shift (anisotropy): The chemical shift results from the shielding of the applied magnetic field by the

electron environment. The shielding causes a slightly different local field at the nucleus and, therefore, a slightly different precession frequency. Since the electron environment depends on the chemical bonds, the measured precession frequency reflects the local chemical environments present in the investigated substance. The chemical shift also depends on the orientation of the molecule with respect to the magnetic field. For powders, noncrystalline or polycrystalline samples, therefore, a broad shift distribution is obtained, the so-called powder pattern. In liquids, motional averaging leads to an isotropic chemical-shift value so that (in the absence of other spin interactions) each chemical site is represented by one line at a characteristic position in the spectrum. The importance of (high-resolution) NMR spectroscopy in chemistry derives mainly from this effect.

Dipolar interaction: The magnetic moments of neighboring spins interact with each other. The resulting dipolar interaction in a strong magnetic field is described in good approximation by the Hamiltonian (given in frequency units), according to Equation (2):

$$H_D = \frac{\mu_0}{4\pi} \sum_{i>j} \frac{\gamma_i \gamma_j \hbar}{r_{ij}^3} \frac{(3\cos^2\theta_{ij} - 1)}{2} (\boldsymbol{I}_i \boldsymbol{I}_j - 3 I_{iz} I_{jz}) \quad (2)$$

where γ_i, γ_j are the magneto-gyric ratios of the spins i, j. The Hamiltonian consists of a spin part which includes the spin operators $\boldsymbol{I}_i$ and $\boldsymbol{I}_j$ (and their z-components) and a geometric part which is a function of the magnitude of the internuclear vector $\boldsymbol{r}_{ij}$ connecting the two spins i, j and the angle θ_{ij} relating $\boldsymbol{r}_{ij}$ to the magnetic field. The two parts can be manipulated by suitable pulse sequences or by mechanical rotation of the sample, respectively. The dipolar interaction normally dominates the solid-state spectrum for ^{1}H nuclei and leads to a line broadening of up to around 50 kHz. This has to be compared with a line width of the order of 10 Hz in liquids where the dipolar interaction is removed by motional averaging.

Quadrupolar interaction: This interaction is present only for nuclei ($I > 1/2$) with a nonvanishing quadrupole moment which interacts with the local electric field gradient present in the sample. The quadrupolar interaction often results in very strong line broadening (>100 kHz). For NMR imaging it is important only in special cases, e.g. for deuterated samples.

2.1.4 Spin Echoes

The evolution of spins under the influence of field inhomogeneity and spin interactions can be refocused by suitable pulse techniques thus generating a spin echo. The most important example with widespread applications in the field of imaging is the Hahn spin-echo sequence shown at the top of Figure 2, by which field inhomogeneities and chemical shifts are refocused.

Figure 2 Hahn spin-echo pulse sequence and its explanation with the magnetization-vector model: (a) situation directly after a 90° excitation pulse; (b) the generated transverse magnetization dephases due to field inhomogeneities and chemical shifts (other spin interactions are not considered). The two vectors **A** and **B** represent "slow" and "fast" components, respectively, and the small arrows indicate the rotation directions with respect to the rotating frame. (c) A 180° pulse is applied which acts on the spins as shown. (d) Component **B** and component **A** are interchanged but remain fast and slow, respectively. Thus a refocusing of the original magnetization takes place. (e) After a time 2τ the original state is re-established and an echo signal is obtained (see upper line). The amplitude of the echo is reduced with respect to the original signal by T_2 relaxation, while the FID is governed by the faster T_2^* relaxation.

As already discussed, the 90°_{-y} pulse creates transverse magnetization in the x' direction of the rotating frame (Figure 2a). The magnetization dephases in the following evolution interval τ due to magnetic-field inhomogeneities and chemical shifts (Figure 2b). At the end of this interval, a 180°_x pulse is applied which flips the spins as shown in Figure 2(c). The spins keep their precession frequencies and directions in the second evolution interval (Figure 2d) and, therefore, refocus after a total time 2τ in the x' direction (Figure 2e). As a result, an echo signal is detected with maximum at 2τ.

Such echo sequences are invaluable for NMR spectroscopy and NMR imaging. They are used, for instance, to overcome the receiver deadtime after a strong rf pulse and, even more important, to gain sufficient time for the spatial encoding during the evolution of the spins (see section 2.2.2). In case of solids, Hahn spin echoes are important only if the decay of the signal is dominated by field inhomogeneities and chemical shifts. The dipolar interaction and relaxation effects due to molecular motions are not refocused by the 180° pulse. The amplitude of the Hahn echo is therefore always reduced compared with the original signal. This so-called T_2 *relaxation* of the spin-echo amplitudes as a function of the echo time has to be distinguished from the T_2^* *relaxation* that characterizes the FID (see pulse sequence, Figure 2).

There are also echo sequences that refocus bilinear interactions, such as the dipolar couplings, generating so-called solid echoes. These sequences will be described later in connection with the corresponding imaging experiments.

2.2 Nuclear Magnetic Resonance Imaging

2.2.1 The Principle

In the following, a brief summary of the basic ideas of NMR imaging is given. More detailed introductions can be found, for instance, in the reference list.[3–5]

NMR imaging is based on the application of a well-defined (constant) magnetic field gradient in addition to the homogeneous main magnetic field $\boldsymbol{B}_0 = (0, 0, B_z)$. Since the latter is much stronger than these additional field contributions, it is sufficient to consider to first order only the three gradient components which have a magnetic-field contribution along the z direction, i.e. $G_x = \partial B_z/\partial x, G_y = \partial B_z/\partial y, G_z = \partial B_z/\partial z$. They are called x, y and z gradients, respectively, and are generated by three perpendicular gradient coils.

The principle of spatial encoding is most easily understood by considering the Larmor condition, Equation (1). If a magnetic field gradient, for instance an x gradient G_x, is applied (see Figure 3a), the magnetic field strength becomes spatially dependent, i.e. $B(x) = B_0 + G_x x$. The precession frequency of the spins therefore varies as a function of their position along the x-axis according to Equation (1) [Equation 3]:

$$w(x) = -\gamma B(x) \tag{3}$$

The signal acquired under influence of an x gradient thus corresponds to a spectrum $I(w) = I[w(x)]$ that represents the spatial distribution of the spins, the one-dimensional projection, in the x direction (see Figure 3b). The spatial information in the NMR signal is encoded in form of frequencies and, therefore, the encoding principle is called *frequency encoding*.

In some experiments, however, the spatial information must be acquired in an indirect way using so-called *phase encoding* (see section 2.2.2 for such an experiment). In this case, the gradient is not applied during the signal acquisition but during an evolution interval τ (see Figure 3c). The coherences thus dephase during the evolution time τ with the frequency $w(x)$. A series of experiments is performed by incrementing τ and acquiring the signal (one point!) at the end (see Figure 3c). The signal that represents the image information is thus acquired pointwise in a series of successive experiments and the resulting data set represents a virtual FID which is spatially encoded in the y direction. Fourier transformation provides the spatial profile which is completely equivalent to that obtained by a frequency encoding procedure. For readers familiar with the concept of 2D NMR spectroscopy, it should be noted that the phase encoding procedure corresponds to the indirect-detection principle of 2D NMR spectroscopy. The only difference is that the gradient is under full control of the experimentalist whereas the spin interactions that are probed in spectroscopy are not. Since phase encoding depends only on the product of phase encoding time τ and gradient strength G, usually the gradient amplitude is incremented instead of the time. This excludes sampling of undesired relaxation effects, for instance the loss of phase coherence by the spin interactions.

A third way to use gradients for spatial selection is *slice selection*. For slice selection, a pulse or a series of pulses (pulse train) is applied in the presence of a gradient. Usually the pulses (or the train) are shaped (designed) such that they have a relatively narrow excitation bandwidth. Therefore, they act only on spins which are located at a narrow frequency range within the wide distribution of precession frequencies $w(x)$ generated by the gradient. The frequency selection now translates into a slice that is perpendicular to the gradient direction.

2.2.2 Multi-dimensional Imaging

Based on the encoding principles discussed above, a wealth of imaging methods have been developed,[3–5] which differ mainly in the way that two- or three-dimensional images are generated. The extension of one-dimensional imaging to two or more dimensions is not as trivial as it might appear at first sight. Simultaneous application of frequency encoding gradients in the x and y directions, for instance, does not result in a two-dimensional image but in a one-dimensional profile along the diagonal as a consequence of the vector superposition.

The most important techniques for overcoming this problem are Fourier imaging and back-projection imaging, which are described below. We confine our discussion to two dimensions but extension to three dimensions is straightforward. Moreover, reduction to two dimensions is often possible using slice selection.

Back-projection imaging is based on the acquisition of a series of one-dimensional projections under different gradient orientations from 0° to (usually) 180°. The reconstruction is performed numerically by sophisticated procedures which involve transformation from cylindrical to Cartesian coordinates and filters for the correction of artifacts. The profiles are usually acquired with a Hahn spin-echo sequence to overcome the receiver deadtime. The frequency encoding gradient is preferably switched off during the application of the pulses to ensure that the whole sample is excited. However, sufficiently fast switching of the gradient is often not possible in solids due to the

Figure 3 Spatial encoding principles in NMR imaging. (a) Frequency encoding: after a 90° excitation pulse, a constant magnetic field gradient is applied and the magnetic-field strength becomes a function of space, i.e. $B_0 = B_0(x)$. (b) The field gradient causes the precession frequency of the spins in the test sample (dark gray) to become spatially dependent along the gradient direction (here the x direction) according to the Larmor condition $w_0(x) = -\gamma B_0(x)$. The measured NMR spectrum (shaded, bright gray) thus corresponds to a spatial profile of the sample in the gradient direction. (c) Phase encoding: after the excitation pulse, the spins evolve in the presence of a gradient for a time τ which is incremented in a series of experiments. The evolution in the presence of the gradient is sampled at the end of each of the evolution periods in the sequence of experiments. The resulting data set thus is acquired point by point in subsequent experiments (1, 2, 3, 4, ...). It is equivalent to that obtained by direct frequency encoding in one shot.

rapidly decaying signal and the finite rise time of the gradient pulses. In this case, the gradients can be left on during the whole sequence provided that the pulses are broad band enough to excite the entire sample irrespective of the presence of the gradient. This makes back-projection attractive for the imaging of solids while in medical imaging these techniques are nowadays seldom used.

Fourier imaging is based on the combination of frequency encoding (direct detection) and phase encoding (indirect detection). As a typical example, Figure 4 shows a 2D Fourier spin-echo sequence. For frequency encoding, a so-called read gradient in the x direction is applied during the signal acquisition (second line, G_x). An x gradient is also present in the first time interval to compensate for the loss of phase coherence by the read gradient. Full compensation is achieved if the shaded areas under the compensation gradient G_1 and the first part of the read gradient G_2 are the same (see Figure 4). In the y direction a phase gradient is applied during the evolution of the spins in the first τ interval (third line, G_y). The amplitude of the gradient is stepped in successive experiments for phase encoding of the spin echoes. Whereas each single echo is frequency encoded in the x direction, the envelope of the echo series

Figure 4 2D Fourier-imaging sequence as a typical example for a two-dimensional imaging technique. It is based on a spin-echo sequence and combines frequency encoding and phase encoding principles (see Figure 3 and text). In the first period of the spin-echo sequence, phase encoding in the y direction takes place while during the acquisition of the echo a frequency encoding gradient in the x direction is applied. In order to avoid undesired dephasing of the coherences by the gradient G_2 before the echo maximum, the gradient G_1 is applied in the first period for compensation (the shaded areas must be equal for full compensation). For the imaging of three-dimensional objects, a slice selection in the z direction can be performed using a frequency-selective 180° pulse applied under influence of a z gradient (see text for further details).

thus contains the information on the phase encoding in the y direction and 2D Fourier transformation directly provides the 2D image. Extension to three dimensions is possible by an additional phase encoding gradient in the z direction. In contrast to frequency encoding gradients, two simultaneously applied phase gradients do not interfere with each other. However, the two gradients must be stepped independently, resulting in a long acquisition time and huge data sets. As an alternative, a slice selection as discussed above can be performed by applying a selective 180° pulse in the presence of a z gradient G_z (see Figure 4).

2.2.3 Spatial Resolution

A detailed discussion of the resolution of NMR imaging was given by Kimmich.[3] Two types of resolution are to be distinguished, *digital resolution* and *physical resolution*. *Digital resolution* or *pixel resolution* can be defined as the separation of two neighboring data points in the frequency domain (which represents the spatial dimension). The frequency interval represented by one data point is $\Delta w_{\mathrm{pix}} = w_{\mathrm{max}}/N$ (where N is the number of data points and w_{max} is the full frequency bandwidth) or, translated in real space, $\Delta x_{\mathrm{pix}} = x_{\mathrm{max}}/N = w_{\mathrm{max}}/(\gamma GN)$, where G is the gradient strength. The pixel resolution thus can be improved by increasing the gradient strength and the number of data points or by decreasing the receiver bandwidth. These possibilities, however, are not independent of each other. For instance, the applicable gradient strength is limited by the available bandwidth into which the profile of the sample has to fit.

More critical than the pixel resolution is the *physical resolution*, particularly in the case of solids. Since NMR is a resonance technique, the physical resolution is determined by the width of the resonance lines, which so far has been neglected. This is well justified in the case of medical imaging where the line widths are only around 100 Hz or less. In polymer materials, however, they extend from several hundred hertz up to around 50 kHz depending on the degree of motional averaging of the anisotropic spin interactions. The measured spatial profile is thus a convolution of the ideal frequency profile representing the image of the sample and the (undesired) intrinsic line width (see Figure 5a and b). The physical resolution in case of frequency encoding is given by Equation (4):

$$\Delta x = \frac{\Delta w}{\gamma G} \tag{4}$$

where Δw is the line width (or the width of the entire spectrum in case of multiple lines). The resolution

Figure 5 Resolution problem of solid-state NMR imaging. (a) Spectrum (left) and spatial profile (right) of the sample in case of a liquid (see gray-shaded sketch). A well-resolved profile is obtained due to the narrow NMR line. (b) Spectrum and spatial profile in case of a solid. The broad solid-state line is convoluted with the ideal shape of the profile [see (a)] which leads to a strong degradation of the resulting spatial resolution.

therefore increases if the intrinsic line width is reduced or if the applied gradient strength is increased. In contrast to most other spectroscopic techniques, reduction of the line width is possible in NMR since the internal spin Hamiltonians can be manipulated by suitable techniques such as sample spinning or rf pulses. As will be discussed in section 4, however, these techniques are sophisticated and simply increasing the gradient strength is often the best solution, in particular for soft solids such as elastomers.

The final resolution of an NMR image is determined by the most unfavorable of the two, pixel resolution and physical resolution, and they should therefore be well balanced. In practice, the pixel resolution should be set to be slightly better than the achievable physical resolution. Both can be improved simultaneously by increasing the gradient strength. However, by increasing the gradient strength (and hence bandwidth), the total signal intensity is distributed over a larger frequency bandwidth. Correspondingly, the intensity within a given frequency interval decreases and the signal-to-noise ratio (S/N) decreases until finally no signal can be detected. The ultimate resolution limit of a volume is therefore given by the S/N. It can be increased to some extent by accumulating a large number n of experiments according to $S/N \propto \sqrt{n}$. In principle, the resolution is thus limited by the available measuring time.

Since NMR is a relatively insensitive technique, the best achievable resolution in conventional NMR imaging experiments is about $10\,\mu m^3$ so that only macroscopic polymer structures are accessible. As already addressed in the Introduction, however, there are several advantages that compensate for the modest resolution, in particular the noninvasiveness of NMR imaging and the possibility of acquiring spatially resolved spectroscopic information.

2.3 Contrast in Nuclear Magnetic Resonance Imaging of Polymers

NMR spectroscopy and relaxometry provide a variety of contrast parameters for the NMR imaging experiment.[16] They can be conveniently combined with NMR imaging to so-called spectroscopic imaging or parameter-selective imaging. Such techniques enable one to observe macroscopic distributions of microscopic material properties and thus to correlate the different length scales.

In spectroscopic imaging, spatial and spectroscopic information are treated as equivalent dimensions. A typical example is a sequence that uses pure phase encoding in two spatial dimensions while the spectroscopic information is acquired in the direct dimension. Spectroscopic imaging is well established in the medical field but so far has only rarely been applied to bulk polymers, where highly resolved spectra are difficult to obtain.

More attractive with respect to polymer investigations is parameter-selective imaging. NMR parameters such as relaxation times are usually related to polymer properties such as molecular dynamics so that the corresponding contrasts directly reflect sample properties. For parameter weighting, a suitable NMR sequence, a so-called filter sequence, precedes the imaging sequence or is incorporated into it. A well known and often used contrast mechanism is T_2 relaxation, i.e. transverse relaxation during the Hahn spin-echo sequence. This sequence filters out predominantly contributions from immobile parts for which motional averaging of the spin interactions is less effective. The filter strength can be conveniently adjusted by choice of the echo time.

With parameter weighting alone, however, it is not possible to distinguish between spatial variations of the contrast parameter and variations of the spin density. In order to discriminate between the two possibilities, a series of images are usually acquired in which the weighting time, for instance, the spin-echo time, is incremented. In analogy with conventional NMR relaxometry, the relaxation time can then be determined for each of the pixels in the image and an image of the T_2 parameter is obtained.

Other filter sequences commonly used for parameter imaging are T_1, $T_{1\rho}$, $T_{2\mathrm{eff}}$, self-diffusion, flow and spin-diffusion sequences, as outlined below.

T_1 can be measured, for instance, by first saturating the initial z magnetization with a 90° pulse and then observing the build-up of new z magnetization with another 90° pulse as a function of the time between the two pulses. T_1 relaxation is a measure of molecular motions of the order of the Larmor frequency, i.e. with correlation times of around 10^{-8} s.

$T_{1\rho}$ is the relaxation time under influence of an rf field applied along the same direction as the initial transverse magnetization. The pulse sequence for measuring $T_{1\rho}$ thus consists of a 90°_x excitation pulse followed by a rf field applied in the y direction for time t. This so-called spin-lock field prevents the magnetization from being dephased by transverse relaxation. If one acquires the signal as a function of the spin-lock time t, however, a decay is still observed. This $T_{1\rho}$ relaxation is sensitive to motions in the order of the amplitude of the spin-lock field, i.e. in the range up to 150 kHz.

$T_{2\mathrm{eff}}$ is the relaxation time under the influence of a multiple-pulse sequence applied for the refocusing of the dipolar interaction. It is sensitive to motions below 100 kHz (see section 4.3).

Transport properties such as self-diffusion or velocities (in the case of coherent flow) can be determined using a magnetic-field gradient but in a somewhat different way as in imaging. In a typical self-diffusion experiment, for instance, a gradient is applied in the first half of a Hahn

Figure 6 Block diagram of an NMR tomograph. More details on the components and on the flow of information is given in the text.

spin-echo pulse sequence causing the magnetization to dephase. After a refocusing pulse, the same gradient is applied again and leads to a refocusing of the coherences. The refocusing is complete as long as the spins remain at the same place, but if they move to another local magnetic field, full refocusing is prevented and the acquired echo amplitude is correspondingly reduced. From a series of such diffusing-weighted echoes acquired as a function of the gradient strength or the echo time, a decay curve is obtained from which the self-diffusion coefficient can be determined. Similar strategies with gradients can be used to encode coherent motions, i.e. flow velocities.[3]

It should be also noted that some of these contrast parameters are sensitive to external influences such as stress and temperature. This enables one to investigate the influence of such effects on material parameters.

2.4 Instrumentation for Nuclear Magnetic Resonance Imaging

An NMR tomograph is an NMR spectrometer which is supplemented with equipment for generating magnetic-field gradients and with software for image processing. Figure 6 shows a simplified block diagram and a brief discussion of the different parts is given below. More details can be found in several monographs.[1–5]

The *spectrometer computer*, a workstation or a personal computer, is used to control almost all operations of the spectrometer. It is usually integrated in a computer network and most data handling can be performed on external computers.

The *transmitter system* provides the rf pulses. It consists of a synthesizer that produces the rf, a modulator and an amplification system. The modulator generates the rf pulses from the continuous radio frequency and from pulse shapes supplied by a pulse generator and by software. The pulses are amplified to the required power of up to 1 kW by (usually two stages of) amplifiers. In case of double-resonance experiments, two separate channels are required, one for each spin species. The transmitter power is transferred to the probe via a receiver-protection circuit (usually crossed diodes) which ensures that the receiver is decoupled from the intense rf irradiation.

The *probe* consists of an rf circuit with a coil that surrounds the sample and with variable capacitors for tuning the coil to the proper resonance frequency. The sample coil is normally used for both excitation and detection of the NMR signal. In the case of solids, the probe is required to support short pulses, short deadtime, sufficient bandwidth, high sensitivity and a sufficiently large sample volume; a good compromise between these requirements has to be found depending on the problem. Commercial microimaging probes, therefore, use removable inserts which allow the optimal coil for a given sample to be used.

The *receiver system*: the NMR signal is picked up by the coil and transferred via the receiver-protection circuit to a preamplifier. After preamplification, the detector separates the transmitter frequency w_0 from the rest of the signal (this step corresponds to the transformation into the rotating frame as discussed in section 2.1). The resulting low-frequency analog signal then is amplified again and digitized. In order to exploit the full dynamic range of the analog–digital converter, the last amplification step is adjustable. Finally, the digitized signal is stored and can be displayed or evaluated.

The *magnet*, usually a superconducting magnet, is the most expensive part of the spectrometer. For materials imaging normally a field strength between 4.8 T (^{1}H frequency of around 200 MHz) and 9.6 T (400 MHz) is used. The magnet bore is usually between 8.9 and 40 cm. The homogeneity of the magnetic field is improved by shim coils which produce small magnetic fields with various dependences on the spatial coordinates. The currents through these coils are adjusted by maximizing the length of the FID of a water test sample and, thus, minimizing the magnetic-field inhomogeneities. In the case of polymer imaging, a careful shim is not important because of the intrinsically broad lines.

The *gradient system* consists of a gradient control unit, gradient drivers and three coils to generate field gradients in the three orthogonal directions. The gradient strength achieved in commercial microimaging systems is usually up to 1–2 T m^{-1}. Details on the design of gradient coils can be found in the literature.[4,5] The gradients normally are applied in the form of gradient pulses. A critical parameter is the rise time, which is optimized by a so-called pre-emphasis unit.

3 NUCLEAR MAGNETIC RESONANCE IMAGING IN SOFT POLYMERS AND RUBBERS

In this section, NMR imaging of polymers with a moderate NMR line width (up to about 3–5 kHz) and of fluids in polymers is described. A full coverage of the literature is not possible within the limited space of this review, and we confine the discussion to some representative examples of the use of NMR imaging in polymer science. We refer exclusively to polymer work although interesting applications to ceramics (liquids or binders), plants and food have also been published.[1,2] More details on the imaging of soft solids can be found in books[1,2] and in further reviews.[6–14] Applications of NMR imaging in process engineering have also been reviewed.[15]

3.1 Imaging of Morphologies

In spite of the modest resolution of NMR imaging, simple (relaxation-weighted) spin-density imaging of morphologies sometimes already provides useful information. This is the case if there are macroscopic structural variations in the density of the sample or if susceptibility artifacts caused by internal interfaces are present. Susceptibility artifacts often enhance contrasts so that, sometimes, structural details are revealed that are below the spatial resolution. For instance, in recent work on elastomers, interfacial layers that result from folding have been studied by taking advantage of susceptibility effects.[17]

An example with high technical relevance is given in Figure 7(a) and (b) [see also Sarkar and Komoroski[18]] where the NMR images of two pieces of car tire (carbon black-filled rubber) are shown. Both structural details and susceptibility effects are visible. The latter is reflected in the image as white spots and results from an inhomogeneous filler distribution (and from the interfaces). A tire piece with poor dispersion of the filler can be clearly recognized in such images. Similar images of tire pieces reveal layers with different types of rubbers so that the composition of the tire can be studied. A different example of a polymer/filler system with technical relevance is given by materials used for solid rocket propellants. NMR imaging reveals the heterogeneous filler distribution in the different parts of propellant samples,[2,19] and also a thin polymer film around the filler particles is found.

As an example of the imaging of porous polymers, Figure 8 shows the image of a polymer foam which was filled with water. The purpose of this or similar experiments is the determination of the distribution of the pores or channels, which is often not possible otherwise since mechanical slicing with sufficient resolution can destroy the foam structure. With 3D NMR imaging, however, the average pore size and the pore size distribution can be determined completely nondestructively. Another interesting application of 3D imaging to porous organic structures is the coarsening of gelatin foams in situ.[20] The pore size distribution can then be evaluated as a function of time. The results show that the coarsening does not develop in a self-similar way.

It is a well-established strategy in NMR imaging of polymers to use liquids as a probe of sample morphologies if otherwise they cannot be imaged because of broad NMR lines. The image of the foam in Figure 8 is one such example as is the work on swollen rubber samples (see below). In a somewhat complementary approach, a liquid can be also used to increase the molecular mobility of the polymer chains so that the sample can be directly imaged. In such cases, deuterated or fluorinated fluids are typically used so that the fluid does not contribute to the image. A drawback of all these techniques, however, is that the swelling can affect the polymer structure so that the nondestructivity of NMR is sacrificed to some extent.

Figure 7 Typical NMR images of tire tread sections, (a) with good dispersion of carbon black and (b) with poor carbon black dispersion. The resolution is 150 × 150 × 350 µm. The spin-echo time was 1.3 ms, the repetition time was 1 s and the total acquisition time of one image was 2 h. Tread grooves are well defined in both sections. The highly uneven appearance in (b) reflects regions of poor dispersion of several hundred micrometers in diameter. [Reprinted with permission from S.N. Sarkar and R.A. Komoroski, *Macromolecules*, **25**, 1420–1426 (1992). Copyright 1992, American Chemical Society.]

Figure 8 3D spin-echo image of a polyurethane foam with an open-pore structure. Before the image was acquired, the foam was immersed in water until all air was replaced. The spin-echo time of the image was set such that only the water signal could contribute to the image. The image intensity was then inverted, so that the water volumes appear black and the foam structure shows up as high intensity. A 3D surface-reconstruction algorithm was applied to the data set to visualize the foam network. The resolution of the image is $30\,\mu m^3$. (Reproduced by Permission of D. Gross, Bruker Analytik, Rheinstetten.)

3.2 Imaging of Material Properties

As already outlined in section 2.3, there are contrast mechanisms other than spin density in NMR imaging. In particular the various relaxation times and the chemical shift enable one to exploit the full strength of NMR spectroscopy for imaging.

As long as it is sufficient simply to discriminate among different parts of a sample, relaxation-weighted imaging can be performed. The easiest way to do this is to prolong the spin-echo time to increase T_2 contrast. Additional contrast can be obtained by applying the more sophisticated relaxation filters that are discussed in section 2.3 and elsewhere.[1,2] In general, relaxation weighting is a convenient means to study mobility contrast. For instance, the phase separation of a blend of polyisoprene (mobile) and polystyrene (more rigid) was studied showing the increase of the more mobile domains with increasing temperature.[21] Also, the segregation of a stearic acid and paraffin model mixture could be studied using simple spin-echo imaging.

For more quantitative information, however, parameter-selective imaging (see section 2.3) has to be used. Such methods not only provide an image of the corresponding parameters but also the true spin density. In particular, NMR relaxation times are sensitive probes of the molecular dynamics and provide excellent contrast in polymer images. Using T_2 relaxation, for instance, inhomogeneities in rubbers have been investigated, with partial swelling of the samples being used to increase contrast.[22] These inhomogenities were then studied as a function of the cure time.[23] Voids and other inhomogeneities that cause susceptibility differences were found as well as morphological defects such as cross-link density inhomogeneities.

The spatial distribution of the cross-link density was studied extensively in swollen[23,24] and nonswollen samples[25–27] using relaxation-time imaging based on T_2 or $T_{1\rho}$ relaxation times. The basis of the image contrast in these studies is that the molecular mobility decreases with increasing cross-link density and thus the relaxation times that are sensitive to slow chain dynamics also decrease. Spatially inhomogeneous cross-link density distributions can be revealed by such NMR imaging experiments.

Oxidative aging is related to changes in the effective cross-link density and can therefore be studied using the same techniques.[21,25,28–30] Early work showed the thickness of the aged layer as a function of the aging time based on relaxation-weighted spin-density and relaxation-time images.[21,25] More recent studies transform these images directly into cross-link density images (see below).[26–30] An extensive (one-dimensional) investigation of the aging of samples with and without aging protectant was described by Fülber et al.[30]

Stress has been investigated using T_2 relaxation of swollen poly(methacrylic acid)–water gel.[31] It was found that the spatial distribution of the spin density and of the water mobility changes under stress, and the mobility of water in the compressed regions was found to be reduced. Nonswollen polysiloxane rubbers were also studied under stress, and filler inhomogeneities and the stress distribution could be imaged.[32] Stress was also investigated in deuterated samples using a contrast based on the generation of double-quantum coherences so that areas with high stress are reflected by stronger signal intensities.[33] Also, the effect of sample heating by external perturbation has been studied using T_2 as a contrast parameter (see section 3.3).

Material scientists, however, are normally not very interested in images of NMR parameters, the interpretation of which often requires a profound knowledge of NMR. Rather, they are interested in the implications of such images with respect to material properties. In early work, therefore, a semiquantitative interpretation was given for T_2 images of swollen samples.[24,31] Following

this line, the measured NMR parameter images can also be directly transformed into images of the corresponding material parameters.[27–32]

The conceptually simplest way to do this is to perform a calibration measurement on a well-characterized series of samples where the investigated material property is varied. This has been exemplified by determining the stress distribution in stretched elastomer samples.[32] For calibration, the transverse relaxation time was measured as a function of the applied stress. The T_2 image of a sample in which a nonuniform stress distribution was induced by a cut could thus be transformed into a stress image (see Figure 9a–c).

Such measurements require a series of calibration samples, which often are not available. In order to avoid calibration measurements, models that relate NMR parameters and material parameters can be used to derive directly the material-property image from the measured NMR-parameter image.[26,27] This approach has been tested on differently cross-linked rubber samples using T_2 and $T_{1\rho}$ imaging sequences. The resulting images have been interpreted using a single-chain model for the T_2 data and a defect-diffusion model for $T_{1\rho}(w)$. Both provide parameters that correspond to the cross-link density and correlation times that characterize slow chain dynamics.[26,27]

As an example, Figure 10(a) and (b) show the cross-link density image of a sample consisting of three pieces of rubber with different cross-link densities. While the different cross-link densities cannot be distinguished in the normal spin-density image (not shown), they are readily distinguishable in the material-property image. The distribution of the cross-link density was analyzed using the corresponding histogram (Figure 10b). Similar investigations were also made for filled rubber samples and for oxidatively aged rubbers,[28–30] where the different aging conditions of the sample parts could be well discriminated by different cross-link densities. Other material properties may be imaged likewise by the use of suitable theories to relate them to measurable NMR parameters. It is expected that this principle will be applicable to a wide variety of problems in the future, building a bridge between NMR spectroscopists and material scientists.

Spectroscopic imaging has seldom been applied to polymers so far because broad lines prevent a satisfactory resolution in most cases. An example where it was nevertheless used was reported by Traub et al.[34] In this work, the lamellar orientation in a sheared block copolymer was investigated in a spatially resolved way. The shear geometry was such that the applied shear amplitude increased along the piece of sample that was used for imaging. From the acquired spectroscopic image it was found that the lamellar orientation changes as a function of the shear amplitude. In another example,[33] the quadrupole splitting of drawn deuterated samples was used as a contrast parameter. By spectroscopic imaging the line splitting in the different areas of the drawn sample could be determined as a function of position and thus a stress map could be obtained. Spectroscopic imaging

Figure 9 Imaging of a rubber sample drawn at $\lambda = 2$ as shown in the sketch. (a) T_2-image as determined from a series of relaxation-weighted images; (b) "strain" map (parameter λ) of the sample obtained from a calibration curve (the contour levels mark changes from $\lambda = 0$ to $\lambda = 3$ in increments of 0.25); (c) "stress" image after re-calibrating with the stress–strain curve of the sample. The stress varies from 0 to 2.1 MPa in increments of 0.3 MPa (adapted from reference 32 with permission).

Figure 10 (a) Cross-link density image of a test sample of three differently cross-linked pieces of rubber evaluated from a series of $T_{1\rho}$ relaxation-time images. Displayed is the parameter d/b which corresponds to the cross-link density in a defect diffusion model (d is the diffusion length between two cross-links, b the width of the defect). (b) Histogram analysis of the d/b distribution of image (a). The three peaks correspond to the different cross-link densities of the three rubber pieces and their widths reflect the cross-link density inhomogeneity of each of them.

has also been applied to more rigid samples, and the corresponding experiments are discussed in section 4.

3.3 Imaging of Processes in Polymers

One of the most fascinating aspects of NMR imaging is that it allows the in situ monitoring of processes in a completely noninvasive way as long as the process takes place within a reasonable time window for the NMR experiment. Examples of processes that have been investigated by NMR imaging are the coarsening of a gelatin foam (see section 3.1), polymerization, vulcanization or cross-linking, aging and the ingress of solvents in polymers (which will be discussed in section 3.4). Some of these investigations are performed on a series of samples which represent various stages of an on-going process, but many are actual in situ investigations.

There have been several studies of the spatial aspects of the polymerization process by NMR imaging. For instance, an investigation of the photopolymerization of hexamethylene dimethacrylate as a function of the photoinitiator concentration has been reported.[35] Also, a series of samples with a different light-exposure time were prepared and studied. Chemical shift resolved imaging techniques were used in this work, but the progress of polymerization was monitored by T_2 contrast reflecting the reduction in molecular mobility due to polymerization. It was found that the transition between polymerized and nonpolymerized regions becomes sharper with increasing exposure time.

The polymerization of methyl methacrylate was studied in situ for two samples with different accelerator contents.[36,37] The progress of polymerization was again monitored by relaxation contrast, in particular T_2 contrast. The image intensities contain qualitative information on the reaction rates, the viscosity and the extent of polymerization in the various parts of the bulk sample.

Using similar techniques, methacrylic acid polymerization was studied together with the progress of a wave front that results from the coupling of molecular diffusion and the chemical reaction.[38] The wave-front reaction zone was found to approximate a δ-function. After an induction period where the polymer front proceeds slowly, the reaction suddenly accelerates and settles down into a constant-velocity wave.

Cross-linking was studied in situ for the case of sulfur vulcanization.[39] A vulcanization device was constructed that could be used in a standard microimaging probe. The field inhomogeneities introduced by the device were dealt with by using a spin-echo sequence and pure phase encoding. Only 1D profiles were acquired to allow the vulcanization process to be followed with a reasonable time resolution. As in many other cases, the experiment could be designed such that 1D profiling is sufficient to obtain the relevant information. Figure 11(a) and (b) show the geometry of the arrangement and the resulting profiles as a function of time after the start of vulcanization. More details on the results of the experiment are given in the caption.

The curing of a continuous carbon fiber-reinforced epoxy resin was studied in situ with 2D imaging.[40] It was started by raising the temperature to the appropriate value and the increase in viscosity as a function of time was monitored via T_2 changes. The curing process was found to be inhomogeneous starting at the sample edges.

Another class of processes that can be studied in situ are those caused by external time-dependent perturbations.

Figure 11 1D in situ imaging of the vulcanization process. An elastomer sample is vulcanized in the NMR spectrometer from the right to the left by applying heat and pressure from this side (see sketch). The profiles are acquired as a function of vulcanization time using a T_2-relaxation-weighted imaging sequence. The first profile (after 5 min) is somewhat larger on the right side as a consequence of the higher temperature and corresponds to the situation before the start of the vulcanization. As soon as the vulcanization takes place, T_2 becomes shorter and thus the signal intensity in the corresponding parts of the sample is reduced. This provides a good means to study the progress of vulcanization as a function of time. [Reproduced by permission from Fülber et al.[39]]

An example is the heating of a filled rubber sample under periodic mechanical load which could be imaged as a function of the shear frequency and the filler content.[41] The image data were acquired synchronized at a given phase of the sine-like mechanical perturbation.

For studies where 1D profiling is not sufficient, fast imaging techniques[3–5] are often useful. These techniques are based on the generation of so-called gradient echoes by reversing the gradient direction. Gradient echoes, however, are limited by T_2^* and are therefore applicable only to relatively mobile systems. An example of the use of fast imaging experiments in material science is the study of the local concentration of suspended particles during a falling-ball experiment.[42] The experiment shows that the concentration of the suspension is higher ahead of the falling ball and that the depleted zone behind the ball never fully recovers in the case of larger ball diameters. The downward velocity was found to decrease as the ball falls owing to the accumulation of suspended particles in front of the ball.

For less mobile cases, a simple one-pulse imaging sequence with back-projection reconstruction has been proposed.[43] As in other fast imaging techniques, a low-angle excitation pulse is applied so that the repetition time can be made very short, of the order of milliseconds. Apart from in situ monitoring of fast processes, such sequences can also be applied for material testing purposes where often it is necessary to have full three-dimensional spatial resolution within a reasonable time. For instance, the sequence described above was first tested on a jellybaby (''gummy bear'') which has a line width of about 2 kHz. A 3D image with 64^3 pixels could be acquired within about a 2 min total acquisition time, in contrast to the hours required for conventional techniques.

3.4 Imaging of Mobile Components in Polymers

One of the strengths of NMR imaging is that it is selective with respect to mobility. The use of fluids for NMR imaging of materials is manifold, and below we discuss a selection of the relevant work.

3.4.1 Distribution of Liquids in Polymers

The distribution of liquids in a polymer can be used as a probe of sample properties. For instance, Figure 12(a) shows an NMR image of the water distribution in the polymer matrix of a microchip which was saturated in a water steam atmosphere at about 390 K for 168 h.[44] The water was found to be distributed homogeneously within the sample. Figure 12(b) shows a slightly different cross-section of the same chip after drying for 11 h. The image reveals that the water distribution now is inhomogenous with little water in the center part. On comparing the two images, it seems that the water does not leave the chip through the surface but through small gaps around the connectors.

Microscopic or mesoscopic properties can be also studied by imaging the distribution of a liquid in a polymer. In early work in this field, the heterogeneous water distribution in polymer composites was shown by 2D NMR imaging.[45] As another example of a heterogeneous water distribution, Figure 12(c) shows the water content of a linoleum sample after 24 h exposure at room temperature. The white spots in the image reflect accumulations of wood fibers whose water uptake is much faster than that of the surrounding polymer matrix. Also, a ''swelling front'' is visible in the image and its progress can be studied as a function of time.

Swelling of a polymer by a solvent is not always motivated by the study of the solvent uptake or the solvent distribution. Nonprotonated solvents are often used to improve the S/N of the image or to enlarge

Figure 12 Images of liquids in a polymer matrix. (a) Image of a silicon microchip saturated with water (3D cross-section). The water is distributed relatively homogeneously within the polymer matrix of the chip (color code from high to low signal: white, blue, green, yellow, red, black). (b) Cross-section of the same sample after drying for 11 h. The water is removed predominantly from the center part. It obviously leaves the chip through small gaps around the connectors [the images are from the investigation described by Hafner and Kuhn[44]]. (c) Water distribution in a piece of linoleum swollen for 24 h at 25 °C. The spots reflect regions with a high concentration of wood fibers. The swelling front can be followed in a series of such images.

structural details by taking advantage of the increased molecular mobility of chains in a swollen state. For instance, the spatial heterogeneity of the molecular mobility of the competitive vulcanization of rubber and polybutadiene blends has been studied using swollen samples.[46] The resulting images showed heterogeneous network formation, which probably is a consequence of the different solubilities of the curatives in the two components.

Not only liquids can be used as probes for material properties but also gases, in particular for the investigation of (internal) surfaces. The use of spin-polarized gases allows one to overcome the S/N problem. An example of such investigations is the imaging of aerogels using ^{129}Xe which was polarized by optical pumping.[47] The application of this technique to polymers was also discussed.

3.4.2 Studies of the Ingress of a Solvent into Polymers

The time dependence of solvent fronts has been studied numerous times for many polymers and solvents.[48–54] Again, we restrict ourselves to representative examples.

In most investigations, the signal of the polymer matrix is filtered out by a spin-echo experiment which takes advantage of the longer T_2 relaxation time of the solvent. The progress of a solvent front can thus be followed easily. In studies of rubbery polymers,[48,49] a diffusion-controlled process was found, that is, normal Fickian

diffusion (case I). Studies of glassy polymers, on the other hand, exhibit case II diffusion.[50] The latter is characterized by a linear uptake of the solvent with time and a sharp front which progresses with constant velocity. In a careful temperature-dependent study it was shown that a change in the transport kinetics from case II (low temperature) to case I takes place at around the effective glass-transition temperature of the system.[51]

Multiple-component diffusion (two solvents) has also been investigated.[48,49] Using the chemical shift to discriminate between the two solvents, the ingress of each of the two components can be studied separately.[48] As an alternative, one of the solvents can also be deuterated.[49] In these investigations it was found that, depending on the mixture and type of the two solvents, they either diffuse at nearly the same rate or two separate diffusion fronts form.

The progress of a solvent front can also be studied indirectly using nonprotonated solvents,[52] while the ^{1}H image of the polymer is acquired. The progress of the solvent is then monitored by its effect on the chain mobility. For this, the echo time is adjusted such that the signal from the nonswollen polymer is suppressed whereas the signal from the swollen parts is preserved because of its higher molecular mobility. This not only allows the study of the progress of a solvent front but also gives direct insight into the changes in molecular mobility of the polymer. Moreover, T_1 relaxation time profiles can also be acquired as a measure of segmental motion and have shown that even after 2 weeks a uniform dynamic equilibrium state has not been reached in a polystyrene sample.[52]

Such studies of the ingress of a solvent have also been made in situ.[52,53] This is particularly simple if nonprotonated solvents are used but discrimination between a protonated solvent and the polymer is also possible if one exploits the differences in relaxation time.[53] In studies with nonprotonated solvents, the polymer and the solvent can be imaged separately. As an example of the latter case, ^{19}F images of a fluorinated solvent where acquired in a polymer.[54] In addition to the investigation of solvent ingress or the swelling of polymers, polymer dissolution can be studied for noncross-linked samples. Such studies have important applications in the investigation of drug release by dissolution of a polymer coating or tablet.[55,56]

3.4.3 Imaging of Transport Properties

In the previous section, transport properties were derived from images of a progressing solvent front. As already discussed in section 2.3, however, there are also NMR techniques for the direct measurement of transport properties such as self-diffusion or flow (i.e. velocities and acceleration).[3,4] These techniques for the measurement of transport parameters can be easily combined with NMR imaging by introducing the corresponding contrast filters, for instance, the self-diffusion filter described in section 2.3. From the pixelwise evaluation of the resulting self-diffusion-weighted imaging series, a self-diffusion-constant image is then obtained.

In such experiments, usually only the self-diffusion constants of mobile components can be determined since the self-diffusion of a polymer chain is too slow to be measurable with the comparatively weak imaging gradients. Polymer properties can therefore be investigated only indirectly using the self-diffusion of the solvent as a probe. The anisotropy of self-diffusion and the restrictions felt by the diffusing molecules provide valuable information on mesoscopic structures in materials. As an example, Figure 13 shows the self-diffusion image of water in a superabsorber particle which consists of a hard shell (highly cross-linked) and a soft core.[57] In the self-diffusion-constant image, the outer part is characterized by lower self-diffusion constants, indicating reduced translational mobility of the water. Further examples of self-diffusion imaging can be found in the literature.[3,4,50]

In a similar way, coherent motion can be also imaged.[58] For instance, the shear of polymer solutions has been investigated by flow imaging (velocity profiles).[59] Transitions from Poiseuille flow to power-law

Figure 13 Self-diffusion image of the water in a fully swollen superabsorber particle. The self-diffusion constant in the shell of the particle is reduced by a factor of about two. It reflects the fact that the outer part of the sample has been additionally cross-linked for mechanical stability. The process that is responsible for the reduction in translational mobility of the water is currently being investigated. [Reproduced by permission from Traub.[57]]

shear thinning have been studied as a function of the polyethylene oxide concentration.[59] In a semidilute solution of high molecular mass polystyrene, strong shear thinning (non-Newtonian behavior) was found and could be interpreted by using a power-law fluid model exhibiting M^3 molecular mass scaling.[60] Flow imaging was also applied to solid–liquid suspensions, which are models for rheological characteristics found during polymer processing.[61] Moreover, the flow of water through mixers and extruders has been monitored by NMR imaging, providing an indirect means to study the geometries used for the extrusion of polymers.[62]

4 NUCLEAR MAGNETIC RESONANCE IMAGING OF RIGID POLYMERS

4.1 Solid-state Imaging Techniques

In the NMR imaging of rigid solids, most efforts have focused on methodological developments to overcome the very broad NMR lines. Not only is the spatial resolution reduced in rigid solids, but also conventional techniques such as the Hahn spin-echo fail and solid-state techniques[63] must be applied. It was therefore only recently that solid-state imaging has reached a state-of-the-art where more advanced techniques can be applied to questions relevant for material science. Because solid-state imaging is still at the stage of development, we will first give a brief overview of the techniques before discussing applications in the following sections. More details can be found in reviews.[6–8,10–14]

4.1.1 Techniques Without Line Narrowing

As already discussed in section 2.2.3, spatial resolution can be increased by using extremely strong gradients or by application of line narrowing techniques. In this section we discuss the first case, that is, techniques that rely on the strength of spatial encoding by the gradient. As a consequence, the total signal intensity is distributed over a large frequency bandwidth so that the S/N is particularly critical in this approach.

4.1.1.1 Strong Gradients and Stray-field Imaging The straightforward approach to increase spatial resolution is the application of an extremely strong gradient. In stray-field imaging,[64–68] the strong magnetic-field gradient in the fringe field of a superconducting magnet is used for this purpose. Stray-field imaging is comparatively simple and therefore attractive with respect to applications. It will be discussed in more detail in section 4.2. As an alternative to such extremely strong static-field gradients, designs for very large pulsed-field gradients have also been realized, and their use has been demonstrated on phantom samples and on plant stems.[69]

4.1.1.2 Multiple-quantum Imaging This approach makes use of coherences that involve correlated flips of two or more spins, so-called multiple-quantum coherences.[70] What makes them interesting for solid-state NMR imaging is that an n-quantum coherence is influenced n times more by an applied gradient than a single-quantum coherence. The spatial resolution should therefore in principle be correspondingly higher.[70] Although conceptually interesting, the technique is so sophisticated that it is not of much practical relevance for ^{1}H imaging in solids so far.

4.1.2 Techniques Based on Line Narrowing

Problems related to the use of extremely strong gradients can be avoided by line narrowing techniques. A trivial way to narrow lines is to raise the sample temperature.[37,71] The line narrowing achieved can be considerable if the sample is heated above its glass-transition temperature. However, other sample properties also change dramatically at this point so that the noninvasiveness of NMR imaging is sacrificed to some extent. The less invasive alternative for reducing the line widths is the use of well-known solid-state line narrowing techniques. Several such line narrowing techniques are presently in use,[63] and all of them have been already applied for the imaging of rigid solids.[6–8,10,13]

4.1.2.1 Imaging with Magic-angle Spinning[72–75] The geometric part of anisotropic spin interactions can be manipulated by rapid sample spinning.[63] The dipolar interaction, for instance, depends on the angle θ_{ij} of the internuclear vector $\boldsymbol{r}_{ij}$ with respect to the magnetic field [Equation 2]. In a powder, all angles θ_{ij} are present and thus a broad line results. For the magic-angle spinning (MAS) experiment, the sample is rotated rapidly so that all interaction components perpendicular to the rotation axis are averaged out for full rotor periods. Choosing the rotation axis along the so-called magic angle of 54.7°, the dipolar interaction vanishes and so does the corresponding line broadening.

MAS line narrowing can be combined with imaging techniques using gradients that are (electronically) rotated in synchrony with the spinning sample.[72–75] In practice, however, ^{1}H MAS imaging is confined to rubbers and other relatively weak solids since the rotor frequencies achieved so far in imaging experiments are not sufficient for efficient line narrowing in rigid solids. Imaging with MAS line narrowing is therefore most useful in combination with other line narrowing techniques or for the imaging of dilute spins such as ^{13}C (see below).

Further drawbacks of the technique are the restriction to small, preferably axially symmetric, samples and possible sample deformation. On the other hand, sample deformation of polymers under centrifugal forces can be studied conveniently by MAS imaging, as was exemplified with a polyisoprene sample.[73] Blends of polystyrene and polybutadiene were also investigated in this work using MAS imaging.

4.1.2.2 Imaging with the Effective Field Along the Magic Angle[76,77] This technique is the spin-space analog to MAS. By applying a suitable off-resonance rf field, the effective field in the rotating frame is aligned along the magic angle in spin space. In a first variant of this technique,[76] the effective field plays the same role in the rotating frame as the static magnetic field does in the laboratory frame. In analogy to the rf pulses, audio-frequency pulses are now applied and their frequency is adjusted to the amplitude of the effective field. They excite coherences that are not affected by the dipolar interaction as long as the effective field is along the direction of the magic angle. Spatial encoding now takes place by a suitable combination of static and rf gradients.

A simpler variant[77] follows the original Lee–Goldburg scheme in which a suitable off-resonance pulse is applied.[63] The component of the initial magnetization which is perpendicular to the effective field evolves in the rotating frame under influence of a combination of a static and an rf gradient. The spatial information is acquired stepwise by incrementing the evolution period, i.e. the length of the off-resonance pulse, which makes this variant a pure phase-encoding technique.

4.1.2.3 Multiple-pulse Imaging[78–84] The dipolar interaction can be averaged in spin space using a suitably designed series of pulses applied on-resonance.[63] These pulses flip the interaction Hamiltonian around the magic angle in spin space such that after cycles of three such flips the average dipolar interaction vanishes to zeroth order and line narrowing is achieved.

Spatial information can be encoded by applying a gradient in the evolution windows between the pulses.[78,79] Although conventional multiple-pulse techniques are demanding, multiple-pulse imaging has already been applied to polymers[80] and to the study of chemical reactions.[81]

A less demanding variant of the multiple-pulse technique[82] is based on the magic-echo sequence.[83,84] We shall discuss this technique in more detail together with its application to polymers in section 4.3. Multiple-pulse line narrowing and MAS line narrowing have also been combined for line narrowing in solid-state imaging,[85,86] but useful applications to polymers are rare because of the high technical sophistication of this experiment.

4.1.2.4 Field-modulation Imaging[87] Line narrowing can be also achieved with a combination of rf irradiation and magnetic-field modulation.[63] The off-resonance sensitivity of this technique leads to slice selection in the presence of a gradient. By moving the sensitive slice across the sample, one can map the spin density.

4.1.2.5 Constant-time Phase-encoding Imaging This approach relies on pure phase-encoding of the spatial information. The phase-encoding gradient is incremented in successive experiments for spatial encoding while the signal is acquired at a fixed time. Thus no signal decay due to undesired line broadening is sampled.[88] The main advantages of constant-time phase-encoding techniques is that they are robust, easy to implement and can be conveniently combined with other NMR techniques.

The drawback of the method in its original form[88] is that in rigid solids the signal decays too fast for reasonable phase-encoding. For modestly rigid solids, however, the technique can provide well-resolved images, as is shown by some applications.[89] The S/N in these experiments can be improved by using low-angle excitation. In this case, T_1 relaxation is no longer a strong limitation, and the repetition time can be made much shorter.[90]

The constant-time phase-encoding technique can also be applied to rigid solids. In this case the fast decay due to the dipolar interaction has to be refocused by generating dipolar echoes.[91,92] Here again, the magic-echo sequence provides the best results,[93–95] and is therefore treated in more detail below together with its polymer applications.

Constant-time phase-encoding techniques were also used in combination with ^{13}C spectroscopy exploiting the fact that with pure phase-encoding techniques the direct dimension can be used for spectroscopic purposes. The spatial distribution of molecular order in drawn polypropylene has been studied by this technique.[96] Deuteron NMR has also been shown to provide useful information in a spectroscopic imaging experiment. For this, constant-time phase-encoding imaging was combined with multiple-quantum imaging.[97] The technique was used for spatially resolved studies of polymer orientation and molecular dynamics taking advantage of the sensitivity of deuteron line shapes to these material properties.

4.1.2.6 Imaging of Dilute Nuclei[75,97,98] The problem of dipolar broadening can be avoided by imaging dilute nuclei such as ^{13}C.[98] In this case, the main line broadening results from the interaction with the abundant proton spins which can be easily removed by heteronuclear dipolar decoupling. As already outlined above, the high spectroscopic information of ^{13}C spectroscopy can be exploited either in static[97,98] or MAS[75] experiments.

The main disadvantage of this approach is the low S/N, which usually prevents satisfactory spatial resolution.

At present, the most interesting approaches with respect to applications are stray-field imaging and constant-time phase-encoding/multiple-pulse line narrowing techniques, in particular those based on the magic-echo pulse sequence. Therefore, we shall discuss them in more detail below and show some representative applications.

4.2 Stray-field Imaging

4.2.1 Principle

In stray-field imaging, the sample is placed in the stray field of a conventional superconducting magnet. The gradient in the stray field of such a magnet is extremely high (of the order of $60\,T\,m^{-1}$). It leads to such a broad distribution of resonance frequencies that even a broadband rf pulse of length 10 μs can only excite part of it. That is, only the signal from a slice perpendicular to the gradient direction is measured. By mechanically moving the sample in the gradient direction, the sensitive slice is moved across the sample and the corresponding signal intensities can be determined as a function of slice position. That is, step by step a spin density profile of the sample is acquired. Two- or three-dimensional images are obtained by stepwise rotation of the sample to determine the profiles in the other directions. For the reconstruction of the image, back-projection techniques can be used (see section 2.2.2).

Since the signal decays rapidly in the strong magnetic field gradient, the magnetization is usually observed in the form of an echo or an echo train. Thus, relaxation contrast can be introduced in stray-field imaging. As an alternative, the S/N can be improved to some extent by adding the echo intensities of an echo train. However, there are problems with such echo trains in strong field gradients. These problems have been extensively discussed in the literature together with strategies to partially overcome them.[66,67]

As in conventional imaging, the resolution of stray-field imaging is ultimately limited by the S/N but also other limitations are present. Apart from technical limitations such as the precision of the stepping motor and the curvature of the sensitive plane, the minimum slice width is determined by the length of the excitation pulse which in turn is limited by the T_2 of the sample. Thus, the resolution in more mobile materials is better than in the case of solid polymers, although even there it is of the order of tens of micrometers. For very mobile samples, self-diffusion limits the resolution so that the best resolution is obtained for quasi-solids such as elastomers.

Several other variants of the stray-field experiment have been developed.[66,67] In the frequency-sweep technique, the sample remains static and the slice is scanned across the sample by changing the rf excitation frequency. A Fourier-transform variant of stray-field imaging also exists. It corresponds to conventional (frequency encoding) imaging except that the static stray-field gradient is used. Since this gradient is extremely strong, a broad receiver bandwidth is required, which limits the application of the technique to very small samples.

4.2.2 Applications

In the following, a brief overview of stray-field imaging of polymers is given with representative examples. More complete recent reviews that include also applications to other materials, can be found in the literature.[66,67] A selection of applications to polymers and other materials, in particular studies of the solvent ingress and of the hardening of materials, can be also found in some of the articles in the book edited by Blümler et al.[2]

One of the early images of a plastic object obtained by stray-field imaging is shown in Figure 14(a). This clearly demonstrates that 3D imaging is feasible with stray-field techniques and provides comparatively good resolution. Nevertheless, most applications of stray-field imaging so far have been one-dimensional. In many cases, the imaging geometry can be arranged such that a one-dimensional experiment already provides the required information.

Stray-field imaging was applied predominantly to topics that were also studied using conventional imaging techniques, e.g. solvent ingress into polymers (see also section 3.4). Unlike these studies, however, stray-field images can represent both the solvent signal and the polymer signal because the technique is largely insensitive to T_2 relaxation. Early studies of swelling were performed on poly(vinyl chloride) swollen by acetone. The solvent ingress was found to follow non-Fickian diffusion laws. Chudek et al.[99] investigated solvent ingress into poly(methyl methacrylate) and the results can be compared with previous results obtained by conventional NMR imaging (see section 3.4).

The opposite of swelling, the drying of films or paints, can be also studied by stray-field techniques, again taking advantage of the insensitivity to T_2 relaxation. It is therefore possible to follow drying processes of initially viscous liquids until they are transformed into brittle glass. For instance, the drying of a latex (paint) film has been studied this way.[68] While the signal remains liquid-like at early stages, T_2 suddenly shortens drastically, preventing other imaging techniques from being used.

Other applications exploit the property that stray-field imaging is fairly resistant to the effects of susceptibility. This can be used to study such unfavorable cases as the

Figure 14 (a) 3D stray-field image of a polycarbonate plug showing that the manufacturing process left air bubbles in the inner parts. The other two images show a mica capacitor before (b) and after (c) burnout. In (b), the intact capacitor plates shield the rf so that no signal from the center parts is acquired. After burnout these plates are destroyed. This example shows that stray-field imaging can be applied to samples that contain metallic parts. (Reproduced by permission of K. Zick, Bruker Analytik, Rheinstetten.)

polymer matrix in an electrical device. As an example, Figure 14(b) and (c) show a mica capacitor imaged before and after burnout, respectively.

4.3 Magic-echo Imaging

4.3.1 Methods

The magic-echo sequence[83,84] is designed such that during a part of the sequence [the *magic sandwich*[84]] the dipolar Hamiltonian has a negative sign. The coherences that have first evolved under influence of the normal dipolar Hamiltonian thus refocus completely during this time and a so-called magic echo appears. In contrast to other solid echoes, the magic echo can be generated for very long echo times, in principle. Although in practice there are technical limitations, the technique nevertheless allows a comparatively long free evolution period for spatial encoding and thus represents the most convenient approach for line narrowing in solid-state imaging. Two variants have been developed on this basis, as follows.

Magic-echo frequency-encoding solid imaging uses homonuclear line narrowing based on the stroboscopic observation of multiple magic echoes.[82] Spatial encoding takes place by gradient pulses of constant strength applied in the windows of the multiple-magic-echo sequence. The phase of the last pulse of the sandwich is changed from $-y$ to y to compensate for the influence of chemical shifts

and field inhomogeneities. The gradient and the receiver phase must then be inverted in every second window. The technique has been demonstrated on solid-state phantom samples of adamantane and hexamethylbenzene (the proton line width at half-intensity of both materials is about 15 kHz) with a reported resolution of better than 100 μm. It was also applied in combination with MAS line narrowing.[86]

Magic-echo phase-encoding solid imaging[93–95] is based on the constant-time approach and uses the magic-echo sequence to prolong the phase-encoding time. As in all constant-time techniques, the residual line broadening does not affect the resolution. The resolution is therefore solely determined by the pixel resolution achievable within the coherence lifetime. Magic-echo phase-encoding is less demanding with respect to instrumentation than the frequency encoding variant. It was demonstrated that images of a remarkably good quality can be achieved even with gradients that are stationary throughout the pulse sequence, so that standard imaging equipment can be used. A resolution of about 100 μm could be achieved with an adamantane test sample. Demonstration experiments with polymers include the imaging of a rubber sample below the glass-transition temperature (the line width at half-intensity exceeds 35 kHz) and the imaging of a plug.[94,95]

The two variants can be combined to form a multiple-magic-echo 2D-Fourier sequence which is the solid-state analog of the conventional 2D Fourier imaging sequence and combines the advantages of the two approaches. A contrast filter preceding the imaging sequence is usually also applied to introduce parameter contrast. The $T_{2\text{eff}}$ relaxation filter was found to be particularly useful for polymer investigations since it is sensitive to molecular motions in the tens of kilohertz regime.

4.3.2 Applications

Despite the sophistication of such experiments, several polymer investigations have been reported. In all of them, a combination of magic-echo imaging with spectroscopic or parameter-selective sequences is essential.

4.3.2.1 Spectroscopic Imaging of Chain Orientations As a first example of spectroscopic magic-echo imaging, drawn polytetrafluoroethylene samples were investigated using ^{19}F-NMR.[100] The ^{19}F spectra show both crystalline and amorphous line contributions. The latter, however, is filtered out under imaging conditions. Drawing of the sample changes the chain orientation and, hence, the chemical-shift anisotropy. The intensity at a certain chemical-shift value can be used as a measure of the applied stress and, applying a chemical-shift imaging sequence, the stress distribution can be mapped as a function of space.

The imaging sequence used in this investigation was a pure phase-encoding multiple-magic-echo sequence with short gradient pulses inserted in the free-evolution intervals. The acquisition of the chemical-shift-resolved spectroscopic dimension takes place in the free-evolution windows of a magic-echo multiple-pulse sequence that eliminates the dipolar interaction but preserves the chemical-shift anisotropy. As a result, a three-dimensional data set is acquired with two spatial dimensions and one spectroscopic dimension. In the spectroscopic dimension, the chemical-shift anisotropy is present and can be exploited for the investigation of orientation dependencies.

An experiment was carried out with a polytetrafluoroethylene sheet in which a cut had been made on one side. After applying tensile stress, a ^{19}F spin-density image and a (normalized) chemical-shift selective image (78 ppm) were recorded. The difference image shows only the regions corresponding to the oriented material. The highest values in the difference image indicate the regions of the strongest strain where the crack eventually occurred.[100]

4.3.2.2 Parameter Imaging of Structure and Mobility in Polymers Various sequences for parameter weighting have been combined with magic-echo imaging, including sequences for measuring the proton spectrum with or without multiple-pulse line narrowing, and filters for T_2, T_1, $T_{2\text{eff}}$ or spin diffusion.[94]

The combination of spin-diffusion experiments with magic-echo imaging allows the measurement of domain-size distributions in an inhomogeneous sample.[101] Thus, macroscopic and microscopic spatial structures can be correlated. As an example, this strategy was applied to cable-insulator material which had been damaged by a high-voltage breakthrough. The spatially resolved spin-diffusion measurement indicated changes of the domain sizes in the affected parts of the cable.

The influence of tensile stress on molecular mobility was investigated using a $T_{2\text{eff}}$ filter sequence. As an example, the molecular mobilities in the necking region of a cold-drawn polycarbonate sample were studied.[102,103] While simple spin-density images show no spatial variations in the material density, an immobilization is found in the necking region. Increasing the stress until the sample starts to break yields an even more pronounced immobilization in two half-moon like regions close to the break (see Figure 15a).

In addition, shear bands can be investigated by the 2D imaging sequence.[103,104] The immobilization of the chains in the shear band is reflected in the $T_{2\text{eff}}$ image while the shear band is not visible in a simple spin-density image. Two crossed shear bands were also visualized by this technique, showing that the immobilization in the intersection of the two is not significantly higher than that in each of them alone (see Figure 15b).

Figure 15 T_{2eff}-relaxation-time images of two pieces of drawn polycarbonate acquired with the magic-echo solid-state imaging sequence. (a) T_{2eff} image of a sample that has been drawn close to the point where it breaks into two pieces; (b) T_{2eff} image of a sample in which two crossing shear bands have been generated. The parameter T_{2eff} clearly reveals the shear band as a region of reduced molecular mobility while the shear bands are not visible in the corresponding spin-density image (not shown). In both cases the rate $1/T_{2eff}$ is displayed. [Reproduced by permission from Traub et al.[34]]

These results demonstrate that, by parameter-selective ^{1}H imaging, material-relevant information can be obtained even in rigid solids. This suggests the applicability of NMR imaging to a wide range of problems in polymer science.

5 SPECIAL TECHNIQUES

5.1 Surface-scan Techniques

Since strong rf pulses are required in solids, there are severe technical limitations on the size of the coil and hence on the sample size. Typical coil diameters used in microimaging are between 5 and 20 mm depending on the required pulse power, that is, on the rigidity of the investigated material.

Considerable efforts have been made to overcome the sample size restriction. The use of surface coils has been proposed for the imaging of larger objects[105] and also devices where the sample can be placed outside the magnet.[106–110] As a prominent example of the latter case, a mobile surface scanner has been described.[107–110] It consists of two permanent magnets separated by a gap where the rf coil is located. The sensitive spot, which consists of a strip of about 3.5 mm along the symmetry axis of the gap, can be scanned over the sample. As in conventional imaging experiments, relaxation studies can be performed. The cross-link density of natural rubber samples has been investigated,[109] and also the stress of a household rubber band. Entire automobile tires can also be investigated despite the presence of ferromagnetic reinforcing steel belts.[107]

5.2 Magnetic Resonance Force Microscopy

Magnetic resonance force microscopy (MRFM) has been proposed for the detection of very small volumes of spins for which conventional NMR techniques are not sensitive enough.[111] This technique promises to be sensitive to the presence of few spins or even to a single spin in the far future so that real microscopic resolution would be achievable.[111–113] The driving motivation behind this technique is thus the perspective to determine molecular structures of biomolecules by direct 3D imaging.[114] In the following, we again restrict ourselves to a brief overview and refer to the literature[114] for more details.

In contrast to the inductive detection used in conventional NMR, MRFM uses mechanical detection of NMR in a force microscope. For this, the sample is fixed on a cantilever and placed in the magnetic field of a permanent magnet. If unpaired electrons or nuclear moments are present in the sample, a force acts on the cantilever. By rf irradiation of the appropriate strength, the magnetization of the sample now is modulated at the resonance frequency of the cantilever so that it starts to oscillate. This oscillation is detected by an interferometry device as the NMR signal.

The applied rf field is able to influence only those spins for which the resonance condition is fulfilled. In a suitably designed inhomogeneous field this is the case only for a given volume of the sample. Shifting the resonance frequency or the position of the sample in the magnetic field thus permits one to scan the resonant volume across the sample.

The technique is currently in an early stage of development but first images have already been recorded. For instance, the one-dimensional image of an ammonium nitrate sample was acquired with a spatial resolution of 2.6 μm.[112] Although ammonium nitrate was chosen because of its favorable relaxation behavior, the experiment is also promising for polymer imaging.

5.3 Volume-selective Spectroscopy

This approach is an alternative to spectroscopic imaging. Whereas in the latter case the full sample is spatially

encoded, spatial information is now introduced by selecting a defined volume element from which the required information can then be extracted by normal NMR spectroscopy.[3] Volume-selective spectroscopy is particularly useful if only selected parts of a sample are of interest or if the quality of the resulting spectrum is of prime importance. Although volume-selective spectroscopy is well established in medicine, applications to materials are rare. Slice selection is particularly difficult for rigid materials since the amplitude of the rf field must exceed the dipolar-coupling strength. Shaped pulses, however, which are normally used for slice selection (see section 2.2.1), are too weak for that purpose.

Nevertheless, first approaches to slice selection in solids have been demonstrated using sequences of broad-band pulses. One technique uses multiple-pulse line narrowing during a frequency-selective multiple-pulse train for selective excitation.[115] The Lee–Goldburg sequence has also been used for slice selection in an imaging experiment.[116] Another approach takes advantage of the frequency selectivity of a spin-lock pulse to select a slice or, applying this technique in all three dimensions, for full volume-selective spectroscopy.[117] As an application of this technique, the orientation of Kevlar fibers in a model sample was determined using the chemical shift as a probe. Finally, the possibility of slice-selective ^{13}C spectroscopy has been demonstrated by taking advantage of the off-resonance sensitivity of the cross-polarization procedure.[118] An overview with more details on these techniques can be found elsewhere.[3]

6 SUMMARY AND FUTURE PERSPECTIVES

During the past 10 years, there has been considerable success in adapting NMR imaging techniques to the investigation of materials. Most of the efforts in the field have focused on method development but, more recently, these efforts were rewarded by a wealth of applications, some even in solids. NMR imaging of polymers is currently in a exciting state where it can contribute already to material research but where future technical advances still hold promise for new breakthroughs.

Despite all methodological efforts, the achievable resolution of the classical techniques will never extend much beyond 10 μm, which is relatively modest compared with other microscopic methods. However, as already discussed, there are several advantages that compensate for this. NMR imaging therefore should not be considered as a competitor of conventional microscopy but as a complement to it. Whereas microscopic techniques are predominantly surface techniques, NMR imaging is a noninvasive bulk technique with high spectroscopic information content. Nondestructivity is certainly not as important for materials investigations as it is for medical applications; nevertheless, it is indispensable for some specialized applications such as the in situ investigation of processes. Moreover, it allows the same object to be investigated further using other techniques.

The main advantage of NMR imaging, however, is the possibility of introducing spectroscopic information. In principle, all information accessible from conventional NMR techniques can also be acquired in a spatially resolved manner and only a few of these possibilities have been realized so far. At present, the high sophistication of some of these methods hampers their accessibility to research groups which specialize in material science rather than in NMR. Nevertheless, interest in these techniques from the polymer industry is noticeable, and some of the examples shown were actually acquired in industrial research laboratories or in cooperation with them. As more material scientists become familiar with NMR imaging, a new step with respect to applications is expected.

ACKNOWLEDGMENTS

I thank R. Komoroski, P. Blümler, B. Blümich, D. Gross and K. Zick for providing figures and the permission to use them in this article. Further, I thank my colleagues B. Traub, F. Weigand, P. Barth, R. Kimmich, D.E. Demco and H.W. Spiess for their excellent collaboration in the field of NMR imaging. Some of the examples used in this article are from this work. I am indebted to S. De Paul and P. Blümler for carefully checking the manuscript and for helpful suggestions.

Solid-state nuclear magnetic resonance (NMR) has emerged as one of the premier methods for polymer characterization in the solid-state. High-resolution spectra can be obtained with cross-polarization and magic-angle sample spinning using equipment that is commonly available on modern NMR spectrometers. Information about the chain structure, conformation, dynamics, intermolecular interactions and the morphology can be obtained by measuring the chemical shifts, line shapes and relaxation times. New experiments have been developed to filter the NMR response such that the spectrum from a particular component can be measured. The resolution has been increased with the development of multidimensional NMR methods for measuring the structure and dynamics. Solid-state NMR experiments can provide the link between the chemical structure and the macroscopic properties of polymers.

1 INTRODUCTION

1.1 Fundamental Principles

NMR spectroscopy is a method of great interest and importance for every aspect of the structure and properties of macromolecules. The first studies were reported by Alpert[1] only about a year after the discovery of nuclear resonance in bulk matter.[2,3] It was observed that natural rubber at room temperature gives a proton line width more like that of a mobile liquid than of a solid, but that the resonance broadens markedly at temperatures approaching the glass temperature. This was recognized as being related to the presence (and cessation) of micro-Brownian motion. NMR methods developed rapidly after these initial observations, and solution-state analysis of polymer microstructure has evolved into the one of the primary methods for the chemical characterization of polymers. With the exception of some early wideline proton NMR studies of polymer dynamics, the development of solid-state NMR for polymer analysis is a more recent development. However, since most polymers are used as solids, the solid-state NMR analysis of polymers has become increasingly important. These studies are of current interest since they can often provide the connection between the molecular structure and dynamics and the macroscopic properties. The methods have become so popular that most modern NMR spectrometers have the capability to perform routine solid-state NMR experiments. The development of new NMR methods is a topic of intense interest that has been driven in large part by the desire to relate the structure and dynamics of polymers measured by NMR to the macroscopic properties.

The NMR phenomenon is possible because in addition to charge and mass, many isotopes possess spin, or angular momentum. Since a spinning charge generates a magnetic field, there is a magnetic moment associated with this angular momentum. According to a basic principle of quantum mechanics, the maximum experimentally observable component of the angular momentum of a nucleus possessing a spin (or of any particle or system having angular momentum) is a half-integral or integral multiple of $h/2\pi$, where h is Planck's constant. This maximum component is I, which is called the spin quantum number or simply "the spin". In general, then, there are $2I + 1$ possible orientations or states of the

nucleus, so if I is $\frac{1}{2}$, the possible magnetic quantum numbers are $+\frac{1}{2}$ and $-\frac{1}{2}$.

When placed in a magnetic field, nuclei having spin undergo precession about the field direction. The frequency of this so-called Larmor precession is designated w_0 in radians per second or ν_0 in hertz (Hz), cycles per second ($w_0 = 2\pi\nu_0$). The nuclei can be made to flip over, i.e. reverse the direction of the spin axis, by applying a second magnetic field, designated B_1, at right-angles to B_0 and causing this second field to rotate at the precession frequency ν_0.

One might suppose that the Larmor precession of the nuclear moments could itself be detected by some means without the need to invoke a resonance phenomenon. This is not possible because each nucleus precesses with a completely random phase with respect to that of its neighbors and there is therefore no macroscopic property of the system that changes at the Larmor frequency. By a well-known relationship, the Larmor precession frequency is given by Equation (1):

$$w_0 = \gamma B_0 \tag{1}$$

where γ is the magnetogyric ratio. The two quantities that determine the observation frequency for NMR signals are the magnetogyric ratio γ and the magnetic field strength B_0. Table 1 list some of the important nuclear properties of spins that are of interest to polymer chemists. The sensitivity depends both on the magnetogyric ratio and the natural abundance of the NMR-active nuclei. Protons have the highest sensitivity because they have the highest magnetogyric ratio and natural abundance. At a field strength of 11.7 T (1 tesla = 10^5 gauss) the NMR signals are observed at 500 MHz. Fluorine is the second most sensitive nucleus, but it is not a common element in polymers. Most polymers of interest contain carbon, and Table 1 shows that the sensitivity is very low compared with that of protons. However, the sensitivity of a modern NMR spectrometer is such that carbon can still be routinely observed. Nitrogen is also a common element in polymers but it is not studied extensively because of its low magnetogyric ratio and natural abundance. ^{15}N-NMR studies are possible, but only after site-specific isotopic labeling. The sensitivity of silicon and phosphorus is intermediate between that of protons and carbons, and provides a valuable probe of those polymers containing these elements.

With the exception of deuterium, all of the nuclei listed in Table 1 are spin-$\frac{1}{2}$. These are the easiest to study because there are line-narrowing methods that make it possible to obtain high-resolution spectra. Deuterium is a spin-1 nucleus with a quadrupole moment. This causes very efficient relaxation and gives rise to broad lines that cannot be narrowed using the common solid-state NMR methods. Thus, while it is difficult to obtain high-resolution deuterium spectra, the characteristic line shapes make this a valuable nucleus for the study of polymer dynamics. Isotopic labeling is required for deuterium NMR studies.

As in all spectroscopy, the signal-to-noise ratio is determined by the energy separation between the levels, and in the magnetic fields employed in NMR instruments, the separation of nuclear magnetic energy levels is very small. For example, for protons in a field of 14.1 T (500 MHz) it is only about 0.5 J. Even in the absence of the radiofrequency (rf) field there is usually a sufficiently rapid transfer of spins from the lower to the upper state and vice versa, such that an equilibrium population distribution is attained within a few seconds after B_0 is applied. For protons this corresponds to a difference of only ca. 10^{-5}. The population difference will be even smaller for nuclei with smaller magnetogyric ratios.

Spin–lattice relaxation is often termed *longitudinal relaxation* because it involves changes of energy and therefore involves the component of the nuclear moment along the direction of the applied magnetic field. It also shortens the lifetimes of the spins in both the upper

Table 1 The NMR properties of nuclei of interest to polymer chemists

Isotope	Abundance (%)	Spin	$\gamma \times 10^{-8}$[a]	Relative sensitivity[b]	ν_0 at 11.7 T (MHz)

and lower energy states. This leads to an uncertainty in the energies of these states and to a broadening of the resonance lines. This can be estimated from the Heisenberg relation, $\delta E\,\delta t \approx h/2\pi$, from which the uncertainty in the frequency of absorption is given by Equation (2):

$$\delta\nu \approx \frac{1}{2\pi\delta t} \tag{2}$$

Although limiting the lifetime of a spin in a given energy state might in principle lead to line broadening, a more important source is the so-called ''dipolar'' broadening. To understand this effect, let us consider a proton-containing solid. In the case where the protons are sufficiently removed from each other that they do not feel the effects of each other's magnetic fields, the resonant magnetic field at the nucleus will be essentially equal to B_0 (actually very slightly smaller because of the shielding effects of local electrons). Therefore, if the field B_0 can be made very homogeneous over the volume occupied by the sample, the width of the absorption peak may be less than 10^{-4} G (10^{-8} T), i.e. of the order of a few tenths of a hertz, or 1 part in 10^9. In most such substances, the protons are actually near enough to each other so that each is appreciably influenced by the magnetic fields of its neighbors. Let us first imagine that we are dealing with a static system of isolated pairs of protons, i.e. each member of the pair experiences the field of the other member but not those of the other pairs. The field felt by each proton will be made up of the applied field B_0, plus this small additional field, B_{loc}. The sign and magnitude of this increment will depend upon the distance separating the nuclei (r) and upon θ, the angle between the line joining the nuclei and the vector representing B_0. Equation (3) expresses the functional dependence of the separation of the protons' magnetic energy levels on the distance r and the relative orientation θ:

$$\Delta E = 2\mu\,(B_0 \pm B_{\text{loc}}) = \; B_0 \pm \tfrac{3}{2}\mu r^3\left(3\cos^2\theta - 1\right) \tag{3}$$

The $\pm$ sign results from the fact that the local field may add to or subtract from B_0 depending upon whether the neighboring dipole is aligned with or against the direction of B_0. We recall that the net polarization of nuclear moments along B_0 is ordinarily only a few parts per million, and so in a large collection of such isolated pairs the probabilities of a neighboring dipole being aligned with or against B_0 are almost equal. Equation (3) expresses the fact that the spectrum of this proton-pair system will consist of two equal lines whose separation, at a fixed value of θ, will vary inversely as r^3. Only when the orientation of the pairs is such that $\cos^2\theta = \frac{1}{3}(\theta = 54.7^\circ)$ will the lines coincide to produce a single line. The spectrum for a hypothetical system is shown in Figure 1(a). Most materials of interest are not macroscopically ordered, so all values of θ are present in the sample, and the spectrum corresponds to an average over all values of θ, as shown in Figure 1(b). The observed line shape is known as a ''Pake'' pattern.

Protons are abundant in most polymers so it is unlikely that pairs of protons are completely separated from their neighbors. A more likely situation is that a proton has several neighbors that differ in both distance and orientation. Each dipolar coupling gives rise to a Pake pattern, but since they all overlap, the spectrum commonly appears as a broad, unresolved line, as shown in Figure 1(c).

We have so far assumed that the nuclei are fixed in position. If *molecular motion* is allowed to take place, i.e. by raising the temperature of the solid, by melting it, or by dissolving it in a mobile solvent, the variables

Figure 1 Schematic diagram of the spectrum from dipolar couplings for (a) an isolated spin pair with a single orientation relative to the magnetic field, (b) a collection of isolated spin pairs with a random orientation relative to the field, and (c) a distribution of distances and angles.

in Equation (3) become functions of time. If we assume that r is constant and only θ varies with time, as would be true for pairs of protons with a rigid molecule, then the time-averaged local field will be given by Equation (4):

$$B_{\text{loc}} = \frac{\mu r^{-3}}{T_2} \int_0^{T_2} \left(3\cos^2\theta - 1\right) \mathrm{d}t \tag{4}$$

where T_2 is the time that the nucleus resides in a given spin state. If θ can vary rapidly over all values, this time average can be replaced by a space average[4] (Equation 5):

$$B_{\text{loc}} = \mu r^{-3} \int_0^{\pi} \left(3\cos^2\theta - 1\right) \sin\theta \, \mathrm{d}\theta = 0 \tag{5}$$

Thus, if the correlation time τ_c is so short that this space averaging is valid, then the net effect of the neighboring magnetic nuclei is effectively erased, and the line will be drastically narrowed (by a factor of 10^4–10^5) compared with its rigid lattice value. If we begin with a solid at a temperature so low that it is virtually a rigid lattice, and then permit molecular motion (chiefly rotation) to occur with increasing frequency by raising the temperature, a narrowing of the resonance line will observed when (Equation 6):

$$\frac{1}{\tau_c} \geq 2\pi\delta\nu \tag{6}$$

where $\delta\nu$ is the static line width (in hertz). In liquids of ordinary viscosity, molecular motion is so rapid that Equation (5) holds; the local variations in magnetic field strength have become so short lived that *motional averaging* is complete.

There is another aspect of the interaction of neighboring magnetic dipoles that is closely related to the effects we have just considered and must also be considered in relation to line broadening. We must recall that our nuclear spins are not merely small static magnetic dipoles, but that even in a rigid solid they are precessing about the field direction. We may resolve a precessing nuclear moment into a static component along the direction of B_0, which we have considered so far, and into a rotating component, whose effect we must now also consider. This rotating component constitutes the right type of magnetic field to induce a transition in a neighboring nucleus if this is precessing at the same frequency. If this spin exchange or flip-flop occurs, the nuclei will exchange magnetic energy states with no overall change in the energy of the system but with a shortening of the lifetime of each. The magnitude of local field variations may be taken as μ/r^3, and consequently the relative phases of the nuclei will change in a time of the order of hr^3/μ^2, the "phase memory time". From Equation (6), we expect an uncertainty broadening of about μ^2/hr^3, i.e. of the same form and order of magnitude as that produced by the interaction of the static components of the nuclear moments. It has become customary to include both effects in the quantity T_2 (Equation 7):

$$T_2 = \frac{1}{\pi\delta\nu} \tag{7}$$

which we defined as the spin lifetime or the spin–spin or transverse relaxation time. A detailed theory of its dependence on molecular correlation time has been given by Bloembergen et al.[5] At short correlation times, as in mobile liquids (where "phase memory" is short), it becomes equal to T_1, but after T_1 passes through its minimum, T_2 continues to decrease as molecular motion becomes slower and finally levels out as the system begins to approach a rigid lattice.

Spin–spin exchange and dipolar broadening should not be considered as merely two alternative ways of looking at the same phenomenon, closely interrelated though they are. For example, in a lattice composed of magnetic nuclei α containing a dilute distribution of a different magnetic nuclear species β, spin exchange between nuclei α and β cannot occur since they precess at greatly different frequencies, but nevertheless, dipolar broadening will be present. Since the spin–spin exchange is very efficient in rigid solids, magnetization can be exchanged over a rather large length scale on the timescale of the spin–lattice relaxation. This process is known as *spin diffusion* and has been successfully used to study the length scale of phase separation in polymers.

From what we have said so far, it might be supposed that at any particular rf w_0 all nuclei of a given species, for example, all protons, would resonate at the same value of B_0. The total range of variation of B_0 for protons is about 13 ppm or ca. 26 500 Hz in a 11.7 T field (500 MHz). This spread in chemical shifts allows for the discrimination based on the chemical structure (methyl, methylene, etc.) and, in favorable cases, for the identification of defect structures. The corresponding ^{13}C spectrum is much larger. In both spectra the intensities of the peaks are proportional to the number of nuclei of each type.

The origin of this variation in resonant field strength is the cloud of electrons about each of the nuclei. When a molecule is placed in a magnetic field B_0, orbital currents are induced in the electron clouds, and these give rise to small, local magnetic fields, which, by a well-known physical principle, are always proportional to B_0 but opposite in direction. Such behavior is common to all molecules and gives rise to the universally observed diamagnetic properties of matter. Each nucleus is, in effect, partially shielded from B_0 by the electrons and requires a slightly higher value of B_0 to achieve resonance.

This can be expressed as Equation (8):

$$B_{\text{loc}} = B_0 (1 - \sigma) \tag{8}$$

where B_{loc} is the actual local field experienced by the nucleus and σ is the *screening constant*, expressing the reduction in effective field. The value of σ is independent of B_0 but highly dependent upon chemical structure.

The causes of variations in nuclear shielding may be thought of as arising from variations in electron density from nearby electron-withdrawing or -donating groups. They are also affected by special shielding effects produced by certain groups and structures that allow circulation of electrons only in certain preferred directions within the molecule. Benzene rings, for example, show this behavior very strongly, and many other groups do so in varying degrees, including even carbon–carbon double bonds. These effects are in general smaller than inductive effects, but nonetheless can be easily observed and can provide valuable structural clues. Protons, because of their low density of screening electrons, show smaller variations than do other nuclei.

It has been observed that the carbon chemical shift depends not only on the type of carbon and attached groups, but also on the chain conformation through the γ-gauche effect. The γ-gauche effect is believed to arise from the proximity of a carbon atom with substituents separated by three intervening bonds (the γ-neighbor). While there is no universal agreement on the origin of the γ-gauche effect, it has been suggested that it arises from van der Waals interactions between the attached hydrogens leading to polarization of the CH bonds.[6] These atoms are closest in the gauche (3 Å) conformation and more distant (4 Å) in the trans conformation. In polymers in solution there is relatively free rotation about the carbon–carbon bonds in the main chain, so many gauche and trans conformations are sampled on the timescale of the carbon chemical shifts and the measured shift depends on the average number of gauche and trans conformers. The measured chemical shift has contributions from all of the γ-gauche interactions. Such conformational averaging is not possible in solids, and the polymer signals are often broadened from a distribution of conformations. This is one of the reasons that the signals for amorphous polymers are often broader than their crystalline counterparts. As might be expected for van der Waals or other types of through-space interactions, the magnitude of the induced shift depends on the group at the γ-position, and more polarizable groups like chlorine and hydroxyl groups have larger effects than do carbon atoms.

The molecular screening constant is actually *anisotropic* or directional, as it depends on the orientation of the molecule with respect to magnetic field direction. It is expressed as a tensor, a mathematical quantity having both direction and magnitude, and is composed of three principal components, σ_{ii} (Equation 9):

$$\sigma = \lambda_{11}^2 \sigma_{11} + \lambda_{22}^2 \sigma_{22} + \lambda_{33}^2 \sigma_{33} \tag{9}$$

where λ_{ii} are the direction cosines of the principal axes of the screening constant with respect to the magnetic field. The principal axis systems may lie along the bond direction, but this is not necessarily so. The orientation of the axis system cannot be predicted a priori, and must be determined experimentally. By convention, the lowest field resonance is taken as σ_{33}. In some cases σ_{xx}, σ_{yy}, and σ_{zz} are used in place of σ_{11}, σ_{22}, and σ_{33}.

If the molecule is oriented so that the principal axis is along the field direction, then the observed chemical shift will correspond to that screening constant. For any arbitrary orientation the chemical shift is prescribed by Equation (9). In solution, the screening constant is given by the isotropic average of this equation. Since this is $\frac{1}{3}$ for each λ_i^2, we have (Equation 10):

$$\sigma = \tfrac{1}{3} (\sigma_{11} + \sigma_{22} + \sigma_{33}) \tag{10}$$

As we shall see, such averaging also occurs when the solid is rotated at the magic-angle.

Most organic solids are polycrystalline, the crystals and their constituent molecules being oriented at all angles with equal probability. Under these circumstances, the screening constant – or chemical shift – takes on a continuum of values forming the line shapes shown in Figure 2(a) and (b). The curve with sharp edges represents the theoretical line shape and the smooth curves represent the experimental line shape, in which a Lorentzian broadening function has been incorporated. Figure 2(b) shows a general, asymmetric powder line shape where the three principal values of the screening tensor all differ. In Figure 2(a) the chemical shift is axially symmetric; the screening constants σ_{11} and σ_{22} are equal and may designated as $\sigma_{\perp}$, σ_{33} being then designated as $\sigma_{\parallel}$. If instead $\sigma_{22} = \sigma_{33}$, as may also happen, the pattern will be reversed left to right. σ_{33} is customarily taken as the smallest value. The observation of such patterns does not actually tell us the orientations of the principal axis of the tensor with respect to the molecular framework. To determine this one must study single crystals or consider symmetry questions and relationships to other known molecules.

1.2 Solid-state Nuclear Magnetic Resonance Methods

1.2.1 Magic-angle Spinning

The NMR spectra of solids are fundamentally different from those in solution, primarily because the polymer matrix inhibits the molecular motion that averages the

Figure 2 Chemical shift anisotropy pattern for (a) axially symmetric and (b) nonaxially symmetric atoms.

chemical shift anisotropy and dipolar interactions and results in sharp lines. Chemical shift anisotropy is a particularly severe problem when observing some nuclei, such as carbon, nitrogen and phosphorus, because they have a large chemical shift range. Most polymer samples are not oriented relative to the field and chemical shifts take on a continuum of values and form the line shapes shown in Figure 2(a) and (b).

The chemical shift anisotropy arises from a non-spherical distribution of electrons that gives rise to an orientation-dependent chemical shift in isotropic samples. In molecules of any degree of complexity there will be several such patterns that may strongly overlap, producing a broad, unresolved spectrum. Under these circumstances it usually becomes necessary to sacrifice the anisotropy information in order to observe a high-resolution spectrum. Under rapid sample rotation the orientations and chemical shifts become time dependent in the rotor period. Taking the time average under rapid rotation gives Equation (11):

$$\sigma = \tfrac{1}{2}\sin^2\beta\,(\sigma_{11} + \sigma_{22} + \sigma_{33}) + \tfrac{1}{2}\left(3\cos^2\beta - 1\right) \qquad (11)$$

where β is the angle between the rotation axis and the magnetic field direction. When β is equal to the so-called magic-angle (54.7°, or the body diagonal of a cube), $\sin^2\beta$ is $\frac{2}{3}$ and the first term becomes equal to one-third of the trace of the tensor (i.e. the isotropic chemical shift) and the $(3\cos^2\beta - 1)$ term is equal to zero. Thus, under magic-angle rotation the chemical shift pattern collapses to the isotropic average, giving the high-resolution spectrum.

The magic-angle spinning spectrum is obtained by taking the sample and packing it in a rotor that can be spun at several kilohertz. The effect of magic-angle spinning on the chemical shift anisotropy pattern is illustrated in Figure 3 for hexamethylbenzene. In addition to the isotropic peaks, spinning sidebands are observed if the sample rotation is not fast compared with the width of

Figure 3 Effect of spinning on the carbon spectrum of hexamethylbenzene at three different spinning speeds. The spinning sidebands for the aromatic carbon are shifted from the isotropic position by the spinning speed.

the chemical shift anisotropy, and these sidebands are offset from the isotropic peak by spinning frequency. The intensities of the sidebands depend on both the spinning speed and the chemical shift anisotropy pattern, and at slow spinning speeds the sidebands trace out the chemical shift anisotropy pattern.

1.2.2 Cross-polarization

A single 90° pulse applied at the resonant frequency produces a free induction decay (FID), and the peak intensities contain quantitative information if we wait for five times the T_1 between scans for the spin system to return to equilibrium. In solids, however, molecular motion is limited and spin–lattice relaxation can be very inefficient. Even in solids that contain rapidly rotating methyl groups, the T_1 values for the other carbons can be prohibitively long. If the T_1s are of the order of hundreds of seconds it becomes difficult to acquire a spectrum with good signal-to-noise ratio if we are forced to wait five times the T_1 between scans.

Cross-polarization is the method most commonly used for signal enhancement in solid-state NMR. It takes advantage of the fact that proton spin diffusion generally causes all of the protons in a solid to have the same T_1, and that the proton T_1s are usually short compared with the carbon T_1s. In the absence of other factors, magnetization transfer between carbons and protons is not very efficient in solids because they have very different resonant frequencies. Cross-polarization works by forcing the proton and carbon signals to precess at the same frequency in the rotating frame even though they do not have the same frequency in the laboratory frame. The means of doing this was demonstrated by Hartmann and Hahn in 1962,[7] when it was shown that energy transfer between nuclei with widely differing Larmor frequencies can be made to occur when Equation (12):

$$\gamma_C B_{1C} = \gamma_H B_{1H} \tag{12}$$

the so-called *Hartmann–Hahn condition* is satisfied. Since γ_H is four times γ_C, the Hartmann–Hahn match occurs when the strength of the applied carbon field B_{1C} is four times the strength of the applied proton field B_{1H}. When the proton and carbon rotating frame energy levels match, polarization is transferred from the abundant protons to the rare carbon-13 nuclei. Because polarization is being transferred from the protons to the carbons, it is the shorter T_1 of the protons that dictates the repetition rate for signal averaging.

Figure 4 shows the pulse sequence diagram the carbon–proton cross-polarization experiment. The pulse sequence begins with a 90_x pulse to the protons to tip them along the y'-axis. The phase of the proton B_1 field is

Figure 4 Pulse sequence diagram for cross-polarization.

then shifted by 90° and the protons are *spin-locked* along the y'-axis for the duration of the spin-locking pulse, and are forced to precess about the y'-axis of their rotating frame with a frequency $w_H = \gamma_H B_{1H}$. Meanwhile, the carbons are put into contact with the protons by turning the carbon field B_{1C} on during the spin-lock time. This causes the carbon magnetization to grow in the direction of the spin-lock field. The carbons are now precessing about their y'-axis with a frequency $w_C = \gamma_C B_{1C}$. Because of this common time dependence, mutual spin flip-flops can occur between protons and carbons, a process that can be visualized as a flow of polarization from the abundant proton spins to the rare carbon spins. It can be shown that under these circumstances the rare spin signal intensity is enhanced by as much as the ratio of magnetogyric ratios of the abundant and rare spins. In the ^1H–^{13}C case this factor is γ_H/γ_C or 4. This is in addition to the great advantage of not having to deal with long carbon-13 spin–lattice relaxation times in spectrum accumulation.

The signal intensity during cross-polarization represents a compromise between several competing processes, including the buildup of intensity from carbon–proton cross-polarization and the decay of the proton and carbons magnetization under the spin locking fields. The intensity at any given cross-polarization contact time t is given by Equation (13):

$$M = \frac{M_0}{T_{1C}} \frac{e^{-t/T_{1\rho}(H)} - e^{-t[1/T_{CH}+1/T_{1\rho}(C)]}}{1/T_{CH} + 1/T_{1\rho}(C) - 1/T_{1\rho}(H)} \tag{13}$$

where T_{CH} is the carbon–proton cross-polarization time constant and $T_{1\rho}(C)$ and $T_{1\rho}(H)$ are the carbon and proton rotating frame spin–lattice relaxation time constants. In most cases $T_{1\rho}(C) \gg T_{CH}$, so Equation (13) simplifies to Equation (14):

$$M = \frac{M_0}{T_{1C}} \frac{e^{-t/T_{1\rho}(H)} - e^{-t/T_{1C}}}{1/T_{1C} - 1/T_{1\rho}(H)} \tag{14}$$

The time course of the magnetization is a rapid buildup in signal intensity due to T_{CH} followed by a slower decay due

Figure 5 Buildup and decay of magnetization in a cross-polarization experiment for samples with (a) short T_{CH} and $T_{1\rho}$(H) and (b) longer T_{CH} and $T_{1\rho}$(H) values corresponding to crystalline and amorphous materials.

to $T_{1\rho}$(H). The signal intensity depends on the relaxation rate constants, which in turn depend on the chain dynamics. It is often observed that the buildup and decay of magnetization are different for crystalline, amorphous and rubbery polymers, and Figure 5 shows the time course of cross-polarization for two very different polymers. It is clear from Figure 5 that the time dependence of the cross-polarization is one way to separate the signals from polymers with different chain dynamics.

1.2.3 Decoupling

The carbon spectrum is often of interest in NMR studies of polymers, but the carbon lines are broadened from dipolar interactions with nearby protons. The dipolar coupling is often strong, and the line widths are of the order of 30–50 kHz. A practical method for the removal of proton dipolar broadening is to employ a high-power proton decoupling field, i.e. *dipolar decoupling*. This is analogous to the decoupling commonly used in solutions to remove the $^{13}C-^{1}H$ scalar couplings, except that much greater power is required.

The line narrowing from dipolar decoupling can be increased by using stronger rf fields, and decoupling fields of 100 kHz are now becoming routine. The limit on the decoupling field is often not the amplifiers, but rather the ability of the probe to take the high power. It has recently been reported that better decoupling can be obtained using lower powers through phase modulation of the decoupling field with the so-called two-pulse phase modulation (TPPM).[8]

1.2.4 Nuclear Magnetic Resonance Relaxation Measurements in Solids

The molecular dynamics of polymers are frequently studied by measuring the NMR relaxation rates that are sensitive the rate and amplitude of molecular motions. The spin–lattice relaxation times of carbons and nitrogens in polymers are of particular interest, but they can be extremely long (of the order of hundreds of seconds). This makes it very difficult to measure using the standard inversion–recovery method, where a waiting time of five times T_1 is required between scans. The carbon T_1s can be more efficiently measured using the cross-polarization T_1 experiment shown in Figure 6.[9] This experiment begins with the standard cross-polarization followed by a 90° carbon pulse to tip the carbon magnetization that was aligned along the y'-axis along the $-$z-axis. Following a relaxation delay (τ) the magnetization is returned to the y'-axis with another carbon 90° pulse, where it is observed with high-power proton decoupling. The greatest advantage of this experiment is that the delay between repetitions is determined not by the carbon T_1s but by the proton T_1s, which are of the order of 1–2 s. In addition, the signal intensity is enhanced by cross-polarization. However, the starting point in the relaxation experiment (after the first carbon 90° pulse) is a nonequilibrium state due to the signal enhancement from cross-polarization. The data are therefore recorded as a difference experiment by changing the phase of the first proton pulse by 180° every other scan and subtracting the FIDs to remove the effects of cross-polarization.

The proton T_1s are also of interest in solids. They are typically not as easy to interpret in terms of the molecular dynamics because of proton spin diffusion, but they provide valuable information about the length scale of phase separation. The proton T_1s can be measured

Figure 6 Pulse sequence diagram for measuring the carbon spin–lattice relaxation using cross-polarization.

Figure 7 Pulse sequence diagram for measuring the proton spin–lattice relaxation rate using cross-polarization.

in the modified cross-polarization experiment shown in Figure 7. This pulse sequence differs from the normal cross-polarization sequence by the application of a 180° proton pulse and relaxation delay period (τ) before the cross-polarization begins. The 180° pulse inverts the proton magnetization and causes the spectrum to appear inverted relative to the equilibrium spectrum. The proton magnetization returns to equilibrium and the relaxation times are extracted using the normal analysis for the inversion–recovery experiment.

A related but distinct experiment enables one to measure the lifetime of the carbon and proton magnetization in the spin-locking field, a quantity characterized by $T_{1\rho}$, the rotating-frame spin–lattice relaxation time. As with the proton T_1s, spin diffusion makes it difficult to interpret the proton $T_{1\rho}$s in terms of the correlation times, but they can provide information about the length scale of phase separation. Under favorable conditions, the carbon $T_{1\rho}$s can provide information about the dynamics of polymers in the kilohertz frequency range that are often directly related to the mechanical properties of polymers.

Figure 8(a) and (b) show the pulse sequences for measuring the proton and carbon $T_{1\rho}$s. There are actually two closely related pulse sequences that can be used to measure the proton $T_{1\rho}$s. One method is to measure carbon intensity as a function of spin-locking time using the cross-polarization pulse sequence shown in Figure 4. The magnetization initially builds up to a maximum due to the carbon–proton dipolar interactions, and the signal decays exponentially to equilibrium with the time constant $T_{1\rho}$(H). Thus the $T_{1\rho}$(H) can be obtained from a semilogarithmic plot of the intensity as a function of spin-locking time after the signals have reached their maximum intensity. An alternative method is shown in Figure 8(a).[10] This pulse sequence differs from the normal cross-polarization in that after the 90° proton pulse the proton spin-locking field is turned on, but the carbon field is not. During this variable period τ, the proton magnetization decays with the time constant

Figure 8 Pulse sequence diagram for measuring the (a) proton and (b) carbon $T_{1\rho}$.

$T_{1\rho}$(H). This decay is monitored by turning on the carbon spin-locking field to initiate cross-polarization followed by signal acquisition. The advantage of this sequence is that the $T_{1\rho}$(H) is obtained from a semilogarithmic plot of the signal decay and nonlinearities in the decay are easier to observe.

The carbon $T_{1\rho}$s are obtained in an analogous manner, as shown in the pulse sequence diagram in Figure 8(b). This pulse sequence begins as the normal cross-polarization with the 90° proton pulse and the spin-locking of the carbons and protons under the Hartmann–Hahn condition. After the carbon signal builds up from cross-polarization, the proton spin-locking field is turned off and the magnetization decays exponentially with the time constant $T_{1\rho}$(C).

1.2.5 Spectral Simplification in Solids

The high-resolution carbon spectra acquired with cross-polarization and magic-angle spinning can contain a large number of signals that can be difficult to assign by simple inspection and comparison to the solution spectra. In addition, there may be spinning sidebands from carbonyl or aromatic groups with large chemical shift anisotropies that overlap with the signals of interest. Hence it is often desirable to simplify the spectra. One simple method used for spectral simplification is *dipolar dephasing*, which is performed using the pulse

Figure 9 Pulse sequence diagram for dipolar dephasing.

sequence shown in Figure 9.[11] Dipolar dephasing differs from cross-polarization only in the variable delay period τ between the cross-polarization and data acquisition periods during which both the proton and carbon spin-locking fields are turned off. Since there is no proton decoupling during this period, the effective line width (and T_2) are those due to the carbon–proton dipolar coupling. The carbons with directly bonded protons have much stronger dipolar couplings and will decay much faster than those without directly bonded protons.

It is frequently not possible to spin polymer samples rapidly enough to remove all the spinning sidebands. Hence the spectra of polymers with several of these signals may be so complex that it is difficult to separate the isotropic signals from the spinning sidebands. While spinning sidebands can contain important information about the chemical shift anisotropy tensor, it is often desirable to simplify the spectrum by removing all but the signals at the isotropic chemical shift. This can be accomplished with the total suppression of sidebands (TOSS) pulse sequence shown in Figure 10.[12] This pulse sequence uses four 180° pulses applied at specific points during two rotor cycles to form echos leading to the

Figure 10 Pulse sequence diagram for sideband suppression using TOSS.

cancellation of all signals except those arising from the isotropic chemical shifts.

1.2.6 Two-dimensional Nuclear Magnetic Resonance

One of the fundamental limitations in solid-state NMR studies of polymers is signal overlap. While good resolution can be obtained with dipolar decoupling and magic-angle spinning, there is often overlap due to the repeating sequence nature of polymer chains and the features of interest, such as defect sites, etc. may not give resolved signals. One way to overcome these limitations is to expand the frequency information into two or more frequency dimensions (*n*D NMR). There are many kinds of *n*D NMR experiments that can be categorized as (a) *correlated* or (b) *resolved* experiments. In correlated experiments the resonance frequency of one signal is related to those of its neighbors and molecular connectivities or distances between atoms can be determined. In resolved experiments the frequency axes show two different interactions. In one kind of resolved experiment, for example, the carbon chemical shift may appear along one axis and the proton line width along the other. Extension of these same principles leads to (3D) NMR experiments in which there are three independent frequency axes. This has the potential of providing still greater resolution for those cases where the (2D) spectrum exhibits overlaps.

*n*D NMR experiments are related to the more familiar experiments in that they consist of a series of pulses and delays. They differ from the more common experiments in that we allow the spin system to *evolve* instead of immediately transforming the FID following the pulse. The pulse sequence for 2D NMR experiments can divided into four periods, *preparation*, *evolution*, *mixing*, and *detection*. During the preparation period, the spins are allowed to come to equilibrium, i.e. the populations of the Zeeman levels are allowed to equilibrate with their surroundings. This interval allows the establishment of reproducible starting conditions for the remainder of the experiment. During the evolution or t_1 period, the x, y, and z components evolve under all the forces acting on the nuclei, including the interactions between them. One of the things that commonly happens during the t_1 period is *frequency labeling*, where the spins are labeled (i.e. prepared in a nonequilibrium state) by their frequency in the NMR spectrum. The mixing period may consist of either pulses or delays and results in the transfer of magnetization between spins that have been frequency labeled in the t_1 period. The final period, t_2, is the signal acquisition that is common to all pulsed NMR experiments. The second frequency is introduced by systematically incrementing the t_1 period. Thus, data collection in a 2D experiment consists in

gathering many FIDs, each obtained with to a different value of t_1. The FIDs are transformed with respect to t_2 to obtain a set of spectra in which the peak intensities or phases are modulated as a function of the t_1 delay. Fourier transformation with respect to t_1 converts the frequency modulation into peaks in the 2D spectrum, which is actually a surface in 3D space and can be represented either as a stacked plot or as a contour plot. *n*D NMR experiments are performed by repeating the evolution and mixing periods $n-1$ times before acquisition. In a 3D experiment, for example, the sequence might be preparation–evolution (t_1)–mixing–evolution (t_2)–mixing–detection (t_3).

1.2.7 Wideline Nuclear Magnetic Resonance

Most solid-state NMR spectra are acquired using cross-polarization/magic-angle spinning (CPMAS) to obtain high-resolution. In some cases, however, it is desirable to measure the wideline spectrum. Little chemical information is obtained in these studies because the lines from different sites overlap, but the averaging of the line shape provides important information about the chain dynamics. Deuterium NMR is the wideline NMR method most often used to study the dynamics because the line shape depend on the rate and amplitude of molecular motion. Deuterium lines have a width of ca. 100 kHz and provide information about molecular motion on this timescale.

The wide lines in deuterium NMR present special experimental difficulties that require the use of special NMR methods. The signals have a very short T_2 and decay quickly after the rf pulses. After the application of a high-powered rf pulse there is a period of time known as the dead time that is required for probe ring down before the signals can be acquired. This is not a problem in high-resolution NMR because the T_2s are long compared with the dead time. However, the deuterium T_2s are of the same order of magnitude as the dead times and most of the signal will decay before the receiver is turned on, leading to an unacceptable distortion in the line shape.

Deuterium spectra can be acquired using the quadrupolar echo pulse sequence shown in Figure 11. The spectra are recorded using an echo so there is a delay period between the pulse and data acquisition to permit probe ring down. The echo delay times are typically of the order of 30 μs, and the spectrometer is adjusted so that the second half of the echo is recorded so the signal can be Fourier transformed in the normal way. In some cases the data are collected before the echo maximum and left shifted prior to Fourier transformation to make sure that data collection is not begun too late. Care must be taken to insure that the line shape and intensity do not change as a function of the echo delay time. This can happen in those cases where the polymer undergoes motion on a timescale near the echo delay time. The spectra are usually gathered at several values of the echo delay time to insure that the line shape is not affected by chain dynamics on this timescale.

Figure 11 Pulse sequence diagram for the quadrupolar echo. The data are acquired after the second delay time τ.

1.2.8 Solid-state Proton Nuclear Magnetic Resonance

Important information about the chain conformation of polymers and the length scale of polymer mixing is contained in the proton solid-state NMR spectra. However, it is difficult to observe the spectra because the lines are broadened by strong dipolar interactions. The proton spectra can be acquired, but only by simultaneously decoupling and observing the proton spectra. This can be accomplished with the method known as CRAMPS,[13] using the pulse sequence shown in Figure 12. Proton decoupling is accomplished with a series of high-power rf pulses that rotate the magnetization quickly along different axes such that on average the magnetization is at the magic-angle. The dipolar couplings have the same functional form as the chemical shift anisotropy and disappear at the magic-angle. If the eight-pulse cycle is fast compared with the dipolar coupling (40 kHz), then the dipolar interactions are averaged and relatively sharp lines can be observed. The data are acquired by sampling a data point after every eight-pulse sequence cycle.

Figure 12 Pulse sequence diagram for combined rotation and multipulse spectroscopy (CRAMPS). The dots show how the data is collected during delays in the multiple pulse sequence.

2 HIGH-RESOLUTION SOLID-STATE NUCLEAR MAGNETIC RESONANCE STUDIES OF POLYMERS

2.1 Introduction

Most uses for polymers are in the solid-state, and understanding the properties of solid polymers has been an important factor driving the development of solid-state NMR methods. These methods have been developed over the past two decades and are now an important part of polymer science. The focus of many of these studies is a molecular level understanding of polymers in their functional state. The resolution of solid-state NMR is less than for solutions, but it has been shown that much useful information can be gathered by this method. As with solution NMR, there have been dramatic improvements in our ability to characterize materials by solid-state NMR with the introduction of 2D NMR and improvements in the NMR spectrometers. Solid-state NMR has become such an important method for polymer characterization that it is now considered a routine characterization tool.

Solid-state NMR has been used for polymer characterization because it can provide information about polymers over a wide range of length scales. On the most detailed level is the information about chain conformation that can be extracted from the chemical shifts. Unlike solution NMR, where the chemical shifts are averaged by molecular motion, the chains are more rigid in solid polymers below T_g, so the chemical shifts [through the γ-gauche effect[14]] reflect the distribution in chain conformation rather than the average chain structure. The organization of polymer chains on a longer length scale (20–200 Å) can be measured using proton *spin diffusion*. In such an experiment the proton signals in one section of the sample (such as the crystalline domains) are excited and magnetization transfer to other domains can be measured. This provides quantitative information because the rate of magnetization transfer depends on the length scale of phase separation.

2.2 Semicrystalline Polymers

A wide variety of NMR methods have been used to study semicrystalline polymers, including the acquisition of carbon, silicon, nitrogen, phosphorus, and proton spectra, NMR relaxation studies and multipulse and other NMR methods. Chain conformation is most commonly studied by carbon NMR with CPMAS. Although carbon has a relatively low sensitivity, it is abundant in most polymers and the spectra can be routinely acquired. Also, since the γ-gauche effect has been extensively studied in polymers,[15] the chemical shifts can provide important information about the chain conformation.

Polyethylene is a commercially important polymer that has been extensively studied by solid-state NMR. Polyethylene exists in an all-trans conformation in the crystalline phase and the spectra have been recorded as a function of crystallinity and sample preparation.[16] Figure 13(a) and (b) show the solid-state spectrum of polyethylene acquired using magic-angle spinning with and without cross-polarization.[17] The largest peak in the cross-polarized spectrum is a sharp resonance at 33.6 ppm that is assigned to crystalline polyethylene in the all-trans conformation, and the broader resonance located at 2.5 ppm to higher field is assigned to the amorphous material. Note that in the spectrum acquired without cross-polarization that the largest peak appears to be the amorphous material, since the relaxation times for the crystalline material are very long and the spectra do not accurately reflect the number of nuclei in the crystalline and amorphous phases. These spectra illustrate how the spectra of a particular phase in a complex material can be emphasized by the proper choice of NMR parameters and experiments, and that extreme care must be taken in the quantitative analysis of these materials. The sample studied in Figure 13(a) and (b) was 68% crystalline by X-ray diffraction.

Figure 13 ^{13}C-NMR spectra of polyethylene acquired with magic-angle spinning and high-power decoupling (a) with and (b) without cross-polarization. (Adapted from McBrierty and Packer[17] by permission of Cambridge University Press, New York. Copyright 1993 American Chemical Society.)

The chemical shifts for the crystalline and amorphous fractions of polyethylene are in accord with those calculated from the γ-gauche effect.[14] In polyethylene in the melt or in solution, about 40% of the bonds are expected to be in the gauche conformation so an upfield shift of 5 ppm is expected. While this prediction is in the right direction, the magnitude of the shift is considerably less than expected. Among the possible explanations for this observation are that chains in the amorphous fractions have a different fraction of gauche bonds than expected on the basis of energy calculations, or that other factors, such as intermolecular interactions, also affect the chemical shifts in the solid-state. It has been observed that the chemical shifts for methylene carbons in *n*-alkanes can vary as much as 1.3 ppm even though they exist in an all-trans conformation.[18]

More recently, 2D double-quantum NMR has been developed as a method to determine the chain conformation in the solid-state.[19] The experiment is performed without sample rotation using ^{13}C-labeled spin pairs, and is similar in principle to the 2D incredible natural abundance double quantum transfer experiment (INADEQUATE) experiment used to measure carbon–carbon connectivities in solution.[20]

The idea behind this experiment is to correlate the chemical shift anisotropy patterns between pairs of carbons that are close in space. As noted in section 1.1, the singularities in the line shape are related to principal-axis system of the chemical shift tensor. For nearby carbons, there exist dipolar couplings that can be measured in the double-quantum spectrum, and the ridge pattern observed in the 2D double–single-quantum correlation spectra will depend on the relative orientations of the tensors in the labeled sites. This leads to a direct determination of the torsional angles.

Figure 14 compares the experimental double-quantum spectrum of polyethylene with the calculated spectra in the trans and gauche conformations.[19] The sample contained 4% doubly labeled polyethylene to minimize intermolecular magnetization transfer, and the spectra were recorded with a rather complex pulse sequence to remove both heteronuclear and homonuclear dipolar couplings during the detection period. The data clearly show the presence of the trans conformation for polyethylene. The amorphous polyethylene signal has been suppressed in these spectra.

The sensitivity of the NMR spectra to chain conformation is particularly striking for isotactic and syndiotactic polypropylene. Both polymers are crystalline, but the isotactic polymer adopts a *...gtgtgt...* 3_1 helical conformation while the syndiotactic polymer forms a 2_1 helix with a *...ggttggtt...* conformation. Half of the methylene groups lie along the interior of the helix in the syndiotactic polymer and are in a gauche arrangement with their

Figure 14 Comparison of the experimental single–double quantum correlation spectrum for polyethylene with simulated data for the trans and gauche conformations. (Adapted from Schmidt-Rohr[19] by permission of Academic Press, Inc. Orlando, FL, USA.)

γ-neighbor, and half the methylene groups lie on the exterior of the helix and are trans to their γ-neighbor.[14] In isotactic polypropylene, the methylene groups are trans to one γ-neighbor and gauche to another. The effects of such conformations are evident in Figure 15(a) and (b) which compare the CPMAS spectra for isotactic and syndiotactic polypropylene.[21] A single resonance is observed for the methylene groups in the isotactic polymer while two resonances separated by 8.7 ppm are observed for the syndiotactic material. This difference in chemical shift for the methylene carbons in the syndiotactic polymer is approximately as large as two γ-gauche effects.[14] The methylene resonance for isotactic polypropylene appears midway between the two peaks in syndiotactic polypropylene, as expected for a methylene group that has one γ-gauche interaction.

The crystal structure in some polymers depends on the crystal growth conditions, and NMR is an efficient way to monitor the state of the sample. This is illustrated in the 20 MHz natural abundance nitrogen NMR spectra for nylon 6 shown in Figure 16(a–c).[22] It is well known that nylon 6 can be prepared in several crystal forms, and it can be seen that significant chemical shift differences are observed between the α- and γ-forms, and that these forms can be identified by their chemical shifts in samples containing a mixture of the two forms. In this case, ^{15}N-NMR is more sensitive to the crystal structure than is ^{13}C-NMR, since it was not possible to distinguish between the two forms in the carbon spectra. Results for many crystalline mixtures have been reported, including those for poly(diethyloxetane)[15] by ^{13}C-NMR and polysilanes[23] by ^{29}Si-NMR.

Chain packing can also effect the chemical shifts of polymers in the crystalline state. Figure 17(a) and (b)

show the effect of crystal packing on the CPMAS carbon spectra of isotactic polypropylene.[24] When polypropylene is annealed above 150 °C, the stable α-polymorph is obtained, while unidirectional crystallization under a

strong temperature gradient yields the β-form. In both forms the chains adopt a 3_1 helix with a *...gtgtgt...* conformation, so the differences in the NMR spectra must result from chain packing effects. Such packing effects are a consequence of the packing of helicies with different handedness in alternate rows in the α-form, while helicies of the same handedness are clustered in the β-form. The 2 : 1 peak intensity ratios for the methylene and methyl carbons in the α-form corresponds to the ratio of nonequivelent packing sites. The two sites have interchain packing distances of 5.28 and 6.14 Å in the α-form and 6.36 Å in the β-form.

Several methods have been developed to differentiate between the crystalline and amorphous materials based on the differences in the cross-polarization dynamics, the T_1s, the $T_{1\rho}$s or the rates of dipolar dephasing in those polymers that have similar chemical shifts in the crystalline and amorphous phases.[25] One of the simplest methods is to use the differences in the spin–lattice relaxation times to increase the relative intensities of the crystalline or amorphous phases. This is accomplished either by choosing a short delay time between acquisitions, such that the crystalline component will be saturated, or by using the CPT_1 pulse sequence and choosing the delay time such that one of the signals is nulled.

Dipolar dephasing can also be used to distinguish between the crystalline and amorphous phases, since one consequence of the more rigid crystalline environment is that the dipolar couplings are much stronger. The important part of the dipolar dephasing pulse sequence is the period after cross-polarization during which the signals decay due to the proton–carbon dipolar interactions.[11] Figure 18 compares the CPMAS spectrum of poly(oxymethylene) with that obtained using dipolar dephasing.[25] In this case, the chemical shift difference between the crystalline and amorphous phases is too small to be observed without such methods. Very similar results have also been reported for poly(ethylene oxide), where the crystalline and amorphous phase can be distinguished on the basis of dipolar dephasing, the T_1 or the $T_{1\rho}$ relaxation times.[26]

2.3 Amorphous Polymers

NMR has been less extensively used to study chain conformation in amorphous polymers because by their nature they are conformationally disordered. However, NMR studies have provided a fundamental insight into the properties and reactivities of amorphous polymers.

The spectral features of amorphous polymers are usually more poorly resolved than are those of crystalline materials, as illustrated in the comparison of the crystalline and amorphous phases of polyethylene as shown in Figure 13(a) and (b). The broadening is due primarily to conformational effects, since there is

a distribution of conformations that are slowly interchanging on the NMR timescale, so the lines are inhomogeneously broadened by the γ-gauche effect. The broadenings are inhomogeneous so the resolution is not improved with higher magnetic fields, as might be expected for small molecules in solution.

Although conformational information is difficult to extract from the CPMAS spectra of amorphous polymers, there are many possible applications for solid-state NMR in the study of amorphous polymers. Solid-state NMR is an important tool to study the curing and reactivity in polymers, such as poly[(phenylsilylene)ethynylene-1,3-phenyleneethynylene]**(1)** which contains Si–H and acetylenic bonds and produces a highly thermally stable polymer by curing above 150 °C.[27] Figure 19 compares the ^{13}C cross-polarization spectra with magic-angle spinning for polymers cured at temperatures up to 400 °C. It is clear from these spectra that the acetylinic carbons with peaks at 87.1 and 107.6 ppm are converted to aromatic material, presumably from a Diels–Alder reaction. ^{29}Si-NMR has also been used to monitor the cure of these polymers.[27]

(1)

2.4 Solid–Solid-phase Transitions

Some polymers are stable in multiple crystalline conformations, and solid-state NMR is an effective means to monitor solid–solid-phase transitions because the changes in conformation are often accompanied by changes in chemical shifts due to the γ-gauche effect or crystal packing effects. 1,4-*trans*-Polybutadiene has long been known to adopt two crystalline forms that can be interconverted with temperature.[28] The form-I conformation is stable at ambient temperature and is well defined by X-ray diffraction. Form-I is reported to have an $s^{\pm}$–t–$s^{\pm}$ conformation for the bonds between the double bonds, where $s^{\pm}$ represents the skew ($\pm 109^{\circ}$) conformation. Form-II is observed above 75 °C, where the chains are packed in a hexagonal array but with a lower density and the equitorial reflections are blurred. Figure 20 shows the effect of temperature on the CPMAS spectrum of 1,4-*trans*-polybutadiene **(2)**, where the conversion from form-I to form-II can be easily followed by NMR.[29] The form-II resonances appear upfield from the form-I peaks, and the mixtures of the two forms can be easily observed at intermediate temperatures. Several models for the form-II conformation have been proposed, including one in which the skew angle is

Figure 19 Solid-state carbon NMR spectrum of poly[(phenylsilylene)ethynylene-1,3-phenyleneethynylene] (a) before curing and cured at (b) 150, (c) 200, (d) 300, and (e) 400 °C. (Adapted with permission from Kuroki et al.[27] Copyright 1998 American Chemical Society.)

decreased from $\pm 109^{\circ}$ to $\pm 80^{\circ}$ to account for the contraction in chain-axis repeat distance observed in the X-ray diffraction.[30] It has also been suggested that the chains are conformationally disordered or that they are rapidly rotating about their long axes.[31] The NMR spectra and relaxation time measurements are most consistent with a model in which the chains are disordered in the form-II conformation.[29] The solid–solid-phase transitions for a number of polymers have been reported, including carbon NMR studies of diacetylenes[32] and silicon NMR studies of polysilanes.[33]

(2)

2.5 Elastomers

The NMR studies of elastomers are fundamentally different from those of other polymers studied by

Figure 20 50 MHz carbon spectra of 1,4-*trans*-polybutadiene as a function of temperature showing the form-I to form-II transition. The spinning sidebands are marked. (Adapted with permission from Schilling et al.[29] Copyright 1987 American Chemical Society.)

solid-state NMR because they are usually studied at temperatures far above their T_g. Under these conditions, the dipolar interactions and chemical shift anisotropy that leads to line broadening are partially averaged by chain motion, and sharp lines are often observed with magic-angle spinning alone. In many cases the motional averaging is such that high-resolution signals can be observed with spinning, and peak assignments can be established using the traditional solution methods. In addition, the lines are often narrowed enough by molecular motion that it is possible to image the samples using magnetic resonance imaging (MRI).

The behavior of elastomers above T_g is illustrated in the proton spectra of *cis*-1,4-polybutadiene shown in

Figure 21 300 MHz magic-angle spinning proton spectra of *cis*-1,4-polybutadiene at several spinning speeds. (Adapted with permission from English.[34] Copyright 1985 American Chemical Society.)

Figure 21.[34] The top spectrum shows that two groups of signals can be resolved in the static proton spectrum, and that each line has a width of ca. 300 Hz. The residual broadening from dipolar couplings and chemical shift anisotropy can be further averaged with magic-angle spinning to 31 Hz. Once the lines have been narrowed by this method, these polymers can be analyzed by any of a number of solution NMR methods. The carbon assignments in elastomers can often be established using the spectral editing methods developed for solution NMR that are based on the number of attached protons and the carbon multiplicity.[35]

The line narrowing in elastomers makes it possible to study their structure by MRI. Imaging is very difficult for most polymers because the resolution in imaging experiments is determined both by the magnetic field gradient strength and the line width. Since the line width for polymers below T_g is of the order of 40 kHz and the T_2s are very short, the signals often decay during the delay periods in an imaging experiment.

NMR imaging is a promising a method that has been extensively used in the medical community, and is now

being used to study the structure of polymers. It has the advantage of being nondestructive and it is not limited to surface analysis or optically clear materials, but has some severe spatial resolution problems in comparison with the imaging of biological samples.[36] The resolution in imaging experiments is limited by the spin–spin relaxation times and line widths, which are much greater for polymers than for the water or fat that is typically imaged in biological samples.

MRI differs from most other NMR methods in that strong magnetic field gradients are used. This is in contrast to most high-resolution NMR studies where the field is made as homogeneous as possible to obtain the highest resolution. The magnetic field gradients are applied so that the resonance frequency for the same atoms can be distinguished if they are at different points in space.

The spatial resolution is obtained by applying field gradients that are deliberately inhomogeneous along the different field directions. The gradient is the spatial derivative of the field and is given by Equation (15):

$$G_l = \frac{\partial Bl}{\partial l} \tag{15}$$

where $l = x, y, z$. The resonance frequency for a spin in the magnetic field is given by Equation (16):

$$w = -\gamma|(1 - \sigma)B_0| \tag{16}$$

where B_0 is the magnetic field, σ is the isotropic chemical shift, and γ is the magnetogyric ratio. In the presence of a magnetic field gradient the frequency becomes a function of spatial position [$\mathbf{r} = f(x, y, z)$] and is given in vector notation by Equation (17):

$$w = -\gamma|(1 - \sigma)B_0 + \boldsymbol{Gr}| \tag{17}$$

This equation shows how the frequency of a resonance in a gradient is modified by its spacial position. This behavior is shown schematically in Figure 22(a) and (b), which compare the spectra for two samples in the presence and absence of a field gradient.[36] The resolution in MRI is determined by the line width and the gradient strength. Two points in space can be resolved if the line width Δw is less than the product of the magnetogyric ratio, the gradient field strength, and the spatial position (Equation 18):

$$\Delta w < \gamma \boldsymbol{Gr} \tag{18}$$

The success of biological imaging is due in large part to the narrow line widths of the water or fat that is imaged. The resolution in polymers will not be as great as in the biological samples, but much useful information can still be obtained.

A variety of pulse sequences have been developed that attempt to overcome the intrinsic imaging limitations

Figure 22 Schematic drawing showing two water samples in (a) a homogeneous field and (b) a homogeneous field with magnetic field gradients. Also shown are the resulting spectra for the two cases.

in solid materials. The choice of the pulse sequence depends on the characteristics of the sample and its NMR properties. The contrast in materials imaging is usually based on differences in relaxation times across the sample to enhance the signals of interest.[36]

Imaging in most materials is performed using 2D NMR methods. The major differences between these experiments and the ones introduced in section 1.2.6 are that MRI uses field gradients during the t_1 period and the acquisition time and the final spectrum is a plot of the intensity as a function of two spatial coordinates. It is possible to obtain 3D images, but more typically selective pulses and gradients are combined to image a plane through the sample.

The line widths in solid polymers are much larger than those for the fat or water signals that are used in biological imaging, and one of the important areas of research is finding new methods for imaging in materials with larger line widths.[37,38] There are many instances, however, where the line widths of polymers

are sufficiently small that the methods used for biological imaging can be used without modification. Among these are the study of liquids in a solid matrix, partially polymerized polymers or polymers at temperatures above T_g. Such studies also provide a valuable insight into voids within solid polymers, rates of solvent diffusion, and polymer flow. Another important area of research is the MRI of rigid solid polymers. Several approaches are currently being explored, including the use of magic-angle spinning[37] and multipulse decoupling.[38] In certain favorable cases, differences in the molecular dynamics or orientations of static samples can be used to obtain useful images.[36]

The quality of the image depends on the instrumental parameters, most notably the time it takes for the spectrometer to recover after a gradient is turned on or off, as well as the line widths and the relaxation times. The data acquisition is often limited by the gradient recovery time, the noisy period following the switching of a gradient on or off during which it is difficult to record a noise-free spectrum. Images are frequently acquired using a Hahn spin echo to detect the signals since the gradient recovery period is placed in the echo delay. This is known as a T_2-weighted image.

Contrast in materials imaging is obtained by taking advantage of the differences in relaxation times across the sample. Differences in the T_2s are most frequently used to enhance the contrast, although differences in T_1s and $T_{1\rho}$s can also be used in favorable circumstances.[39] Figure 23(a–d) show cross-sections through images of a tire tread containing natural rubber and styrene–butadiene rubber using the differences in the relaxation times to enhance the contrast of one material over the other.[39] The contrast differences are due to differences in relaxation times that are related to the differences in the molecular dynamics of the natural rubber and the styrene–butadiene rubber. The differences in the T_1s are not large enough to give contrast enhancement of one component over the other. In experiments where the image is weighted by the T_2 or the $T_{1\rho}$ relaxation times, more intensity is associated with the natural rubber relative the styrene–butadiene rubber, and natural rubber appears brighter in the final image.

The NMR imaging of elastomers has been used to investigate the morphology, composition, and defects in composite materials such as non-steel belted radial tires. Figure 24 shows an image of a cross-section through a tire in which the elastomer can be distinguished from the reinforcing fibers that have a much shorter T_2 and appear as dark circles in the T_2-weighted image.[40] The resolution in this experiment is ca. 200 μm and the image has some distortions due to the magnetic susceptibility variations associated with the voids and

Figure 23 Cross-sections through an image of styrene–butadiene rubber and natural rubber obtained with different filtering pulse sequences applied before the imaging pulse sequence. The data are shown for (a) the T_1 filter, (b) the T_2 filter, (c) the dipolar filter and (d) the $T_{1\rho}$ filter. (Adapted from Blumler et al.[39] by permission of Elsevier Science, Oxford, UK.)

filler particles. It was also shown that the variations in intensity of the elastomeric portions are associated with composition variations in the rubber, and it is estimated that a 20% variation in the composition of the *cis*-polybutadiene/styrene–butadiene rubber can be identified in the T_2-weighted image.

2.6 Other Studies

Solid-state NMR methods are used to study a wide variety of polymeric materials in addition to the crystalline, amorphous and rubbery polymers discussed above. Some of these materials have molecular dynamics like

Figure 24 NMR image of a non-steel belted radial tire section. The bright portions of the image are due to the elastomer. (Adapted with permission from Sarkar, Komoroski.[40] Copyright 1992 American Chemical Society.)

elastomers and can be studied using the methods discussed in section 2.5. Among the materials of interest are gels, inclusion compounds, cross-linked polymers, polymers above T_g, melts, and ionomers. The NMR method of choice depends mainly on the molecular dynamics of the material under study. Since many of these materials are more mobile than rigid solids, cross-polarization and magic-angle spinning may not be the methods of choice.

Swollen cross-linked polymer gels are a class of materials that have chain mobilities intermediate between those of solids and liquids. One important example of these materials are the polystyrene derivatives that are often used for solid phase synthesis of peptides and other biomolecules. Figure 25(a) and (b) compare the static and magic-angle spinning proton NMR spectra of a derivatized poly(styrene–divinylbenzene) cross-linked gel swollen in chloroform.[41] The lines are effectively narrowed by magic-angle spinning and the resolution is comparable to that obtained for polystyrene in solution without cross-linking. A similar sharpening in the carbon spectra was also reported.[41] Since a liquid-like spectrum is observed with spinning, these materials can be characterized using the 1D (one-dimensional) and 2D methods developed for polymer characterization in solution.

The inclusion compounds formed between some polymers and certain matrix materials are another class of materials with mobilities intermediate between

Figure 25 (a) Static and (b) magic-angle spinning proton NMR spectra of a derivatized poly(styrene–divinylbenzene) swollen in chloroform. (Adapted with permission from Stover and Frechet.[41] Copyright 1989 American Chemical Society.)

solutions and rigid solids. It has been observed that some small molecules, such as perhydrotriphenylene or urea, form stable crystal structures in which long-chain polymers are included into narrow channels. Solid-state carbon NMR has been used to study a number of such inclusion compounds, including those formed between perhydrotriphenylene and polyethylene,[42] *trans*-1,4-polybutadiene[43] and *trans*-1,4-polypentadiene.[44] Figure 26 shows the CPMAS spectrum of the perhydrotriphenylene – polyethylene inclusion compound.[42] As noted in section 2.2, polyethylene exists in an all-trans conformation in the crystalline phase and the methylene carbon resonance in the amorphous phase is shifted upfield by 2.5 ppm due to the presence of ca. 40% of the bonds in the gauche conformation. The chemical shift for the polyethylene inclusion compound (33.6 ppm) is the same as for the crystalline phase, demonstrating that the polymer exists in an all-trans conformation in the narrow channel. Since the relaxation

Figure 26 100 MHz carbon NMR spectrum of the polyethylene – perhydrotriphenylene complex obtained with magic-angle spinning and dipolar decoupling. The peaks labeled 1, 2 and 3 are assigned to the matrix. (Adapted with permission from Sozzani et al.[42] Copyright 1991 American Chemical Society.)

times for the polymer and the matrix material differ, it is possible to choose experimental conditions to enhance the signals from either the polymer or the matrix.[42]

3 THE SOLID-STATE ORGANIZATION OF POLYMERS

3.1 Introduction

NMR studies have been valuable not only to study the local structure or conformation of polymer chains, but also to measure the order over larger length scales. These measurements are made primarily by selective excitation of one portion of the sample (i.e. the rigid or mobile phase) and measuring the rate of spin diffusion to the other phase. If the intrinsic spin diffusion rate is known, then the average distance between the phases can be calculated for an assumed morphological model.

In most cases the selective excitation is based on a difference in the relaxation rates between the phases. In semicrystalline polymers, for example, there is typically a large difference in the spin–spin relaxation rates between the rigid crystalline and the more mobile amorphous phases. Therefore, if the magnetization from atoms in both phases are tipped into the xy plane, the signals from the rigid material with the short T_2 decays rapidly, leaving only the signals from the mobile phase. This is the basis

Figure 27 Pulse sequence diagram for the Goldman–Shen experiment.[45]

for the most commonly used pulse sequence to study the domain structure, the Goldman–Shen pulse sequence shown in Figure 27.[45] Following the initial 90° pulse, the magnetization from the rigid phase decays to zero due to T_2 relaxation during the delay period τ_0 whereas the magnetization from the mobile phase does not. The magnetization from the mobile phase is returned to the $+z$-axis with a pulse of opposite phase to the first one, creating a spin state in which the mobile phase is close to equilibrium, while the rigid phase is saturated. If the rigid and mobile material are in close proximity then the rigid phase can relax by magneitzation transfer to the mobile phase. The signals are observed by the final 90° pulse, and the data are typically acquired for several values of the spin diffusion delay time τ_m. In such an experiment the rigid signals will increase as a function of τ_m whereas mobile signals will decrease as a result of spin diffusion from the rigid to the mobile phase.

Information about the domain structure of polymers is obtained by solving the diffusion Equation (19):

$$\dot{m}(r,t) = D\nabla^2 m(r,t) \tag{19}$$

where D is the diffusion constant ($cm^2\,s^{-1}$) and $m(r,t)$ is the local magnetization density. The solutions to this equation are expressed in terms of the response function $R(t)$, which can be obtained from the measured intensities as a function of time[46] (Equation 20):

$$R(t) = 1 - \frac{M(t) - M(\infty)}{M(0) - M(\infty)} \tag{20}$$

where M is the intensity of the rigid portion of the material. The expression for $R(t)$ depends on the boundary conditions and on the dimensionality. The simplest cases are for 1D, 2D, and 3D diffusion, where $\bar{b}$ is taken to be the average domain dimension. For 1D diffusion, $R(t)$ is given by Equation (21):

$$\begin{aligned} R(t) &= 1 - \phi(t) \\ &= \left(\frac{2}{\sqrt{\pi}}\right)\left(\frac{Dt}{\bar{b}^2}\right)^2 \qquad \text{for } t \ll \frac{\bar{b}^2}{D} \\ &= 1 - \sqrt{\pi}\left(\frac{\bar{b}^2}{Dt}\right) \qquad \text{for } t \gg \frac{\bar{b}^2}{D} \end{aligned} \tag{21}$$

For 2D diffusion the expression for $R(t)$ is given by Equation (22):

$$\begin{aligned} R(t) &= 1 - \phi(t)^2 \\ &= \left(4\sqrt{\pi}\right)\left(\frac{Dt}{\bar{b}^2}\right)^{1/2} \qquad \text{for } t \ll \frac{\bar{b}^2}{D} \\ &= 1 - \sqrt{\pi}\left(\frac{\bar{b}^2}{\pi Dt}\right) \qquad \text{for } t \gg \frac{\bar{b}^2}{D} \end{aligned} \tag{22}$$

and for 3D diffusion the result is Equation (23):

$$\begin{aligned} R(t) &= 1 - \phi(t)^3 \\ &= \left(6\sqrt{\pi}\right)\left(\frac{Dt}{\bar{b}^2}\right)^{1/2} \qquad \text{for } t \ll \frac{\bar{b}^2}{D} \\ &= 1 - \left(\frac{\bar{b}^2}{\pi Dt}\right)^{3/2} \qquad \text{for } t \gg \frac{\bar{b}^2}{D} \end{aligned} \tag{23}$$

Physically, 1D diffusion applies to layer-like or lamellar structures, 2D diffusion is most applicable to rod-like structures, and 3D diffusion applies to spheres or cube-like structures. Figure 28 shows a plot of the response function against $\sqrt{\tau}$, which is equal to $\sqrt{Dt}/\bar{b}$, for 1D, 2D, and 3D diffusion.[46]

Spin diffusion is an important tool for measuring the length scale of phase separation in semicrystalline polymers, blends and a wide variety of phase-separated materials. These studies have increased our understanding of phase separation in polymers, but it should be noted that the domain sizes measured in these experiments can only be considered estimates because the values depend on estimates of the diffusion coefficients and the morphological models. Real polymers, for example, might not correspond to the 1D, 2D, or 3D models listed above. It is sometimes necessary to use more sophisticated morphological models that include an interface with a rate constant for spin diffusion that is intermediate between the rigid and amorphous phases.[47] These models, of course, have a larger number of adjustable parameters. It is also possible to derive analytical solutions for spin diffusion in defined geometries, but again, the solutions can be complex and it may not be possible to distinguish between the various models from the shape of the spin diffusion recovery curves. It has been suggested that the initial rate measurements are an easy and reliable way to measure domain sizes in binary mixtures.[48]

Figure 28 Response function $R(\tau)$ for the recovery of magnetization in the Goldman–Shen experiment for 1D, 2D, and 3D diffusion as a function of the diffusion time. (Adapted with permission from Cheung and Gerstein.[46] Copyright 1981 American Chemical Society.)

The determination of the diffusion constant used to calculate the domain sizes is an important consideration. In most experiments the rigid phase has a shorter T_2 and is saturated during the τ_0 delay in the Goldmen–Shen pulse sequence, so the rate-limiting step in spin diffusion is the spread of magnetization in the mobile phase. In such cases the spin diffusion depends only on the rate of spin diffusion in the mobile phase.

In the earliest studies the rate constants for spin diffusion were estimated from T_2 relaxation rates for the more mobile phase. The spin diffusion rate constant can be estimated from Equation (24):[49]

$$D = \frac{2r_0^2}{T_2} \tag{24}$$

where r_0 is the radius of the hydrogen atom. This value was successfully used to estimate the domain sizes in polyurethanes that were independently measured by X-ray scattering.[49] The upper bound for D can also be estimated by Equation (25):[46]

$$D = \frac{13a^2}{T_2} \tag{25}$$

where a and T_2 are the average distances between protons and the spin–spin relaxation time for the less mobile phase. This estimate was validated in a study of semicrystalline polymers.[46]

In some instances it is possible to determine the spin diffusion constants by measuring spin diffusion in a system where the length scales have been determined by some other experiment. This was reported for symmetric diblock copolymers of styrene and methyl methacrylate that are known to form lamellar structures.[48] In this study the rates of spin diffusion were measured and the diffusion constant was treated as an adjustable parameter to obtain the best agreement with the domain sizes measured by transmission electron microscopy and small-angle X-ray scattering. Excellent agreement between

the NMR and scattering data was obtained using a value of $0.8 \times 10^{-12}\,cm^2\,s^{-1}$ for the glassy phases of both the styrene and methyl methacrylate blocks. The relationships between the line widths or T_2s and the spin diffusion coefficients are known to be approximately correct for rigid materials, but seriously in error for very mobile materials.[50]

In the early measurements of domain sizes by NMR, the spin diffusion data were acquired using proton wideline NMR and fitting the FID to two decay processes that were assigned to the rigid and mobile phases. More recently, variants of the Goldman–Shen pulse sequence have been developed to measure spin diffusion in high-resolution spectra. The simplest application is to follow the spin diffusion period with a cross-polarization pulse sequence to detect the high-resolution carbon spectrum. Pulse sequences such as the dipolar filter,[51] chemical shift filter[52] or chemical shift gradients[53] can be used to create a difference in spin temperature for the two components under study. Selective excitation[54] and 2D CRAMPS NMR[55] have also been used for these studies, as have various types of solid-state carbon–proton 2D NMR methods. Several of these methods will be discussed in the following sections.

Figure 29 Response function $R(t)$ plotted as a function of $\sqrt{t}$ for polyethylene. The solid lines are calculated for 1D, 2D, and 3D diffusion. (Adapted with permission from Cheung and Gerstein.[46] Copyright 1981 American Chemical Society.)

3.2 Semicrystalline Polymers

Solid-state NMR methods have made important contributions to our understanding of the organization of semicrystalline polymers, in part because the length scales that can be measured by spin diffusion and other techniques are smaller than those that can be measured by microscopy. These methods are also nondestructive and are relatively easy to perform.

The domain sizes of the crystalline and amorphous fractions of polyethylene have been characterized by several spin diffusion methods. In an early study the domain sizes in polyethylene were measured using the Goldman–Shen pulse sequence.[46] The difference in spin polarization between the crystalline and amorphous fractions was produced with a 42 μs delay between the first two 90° pulses of the Goldman–Shen pulse sequence, and the data were acquired as a function of τ_m. The FIDs were fitted to Gaussian and Lorentzian components that were assigned to the crystalline and amorphous phases. The recovery factor $R(t)$ is plotted in Figure 29 along with the best fits from the 1D, 2D, and 3D morphological models. Although polyethylene is known to have a lamellar morphology, the spin diffusion data for the noncrystalline domains appear to be better described by a 2D or 3D model. Using the diffusion coefficient of $8.3 \times 10^{-12}\,cm^2\,s^{-1}$ the average domain spacings for the 2D and 3D models were calculated to be 90 and 144 Å, respectively. As discussed below, more complex morphological models that incorporate interfacial regions might provide a more realistic model for spin diffusion in lamellar semicrystalline polymers.

The structures of other polyethylene samples have been investigated more recently using the dipolar filter pulse sequence to create the polarization difference between the crystalline and amorphous fractions, which can then be monitored by the carbon spectrum using magic-angle spinning and cross-polarization.[51] The pulse sequence used in these studies is shown in Figure 30. The dipolar filter part of the pulse sequence is a multipulse sequence designed to average the dipolar couplings. However, in the dipolar filter experiment the delay time τ between pulses is longer (7–20 μs) than for multipulse decoupling experiments. The dipolar couplings in the rigid phase are not averaged under these conditions, and these signals are saturated by applying the sequence several times, while the signals from the mobile phase are perturbed to a much smaller degree. Following the spin diffusion time, the proton magnetization is sampled with the cross-polarization. This approach has the advantage that the carbon spectrum is observed, where the resolution is typically much greater than in the proton spectrum.

Both low- and high-density polyethylene were studied by this using the dipolar filter. Figure 31 shows a plot of the spin diffusion data for low-density polyethylene.[56] The data could not be adequately fitted to a simple two-phase model, indicating that there may be a substantial interfacial component that was not detected in the earlier

Figure 30 Pulse sequence diagram for the dipolar filtering experiment detected by cross-polarization. The dipolar filter is a multipulse sequence that averages the dipolar couplings of the mobile phase while saturating the signals of the rigid phase. After a spin diffusion period (τ_m) the magnetization is measured using cross-polarization.[51]

Figure 31 Spin diffusion in low-density polyethylene measured by the dipolar filter. Note the rapid spin diffusion from the more mobile to the less mobile amorphous materials in the first 5 ms followed by a slower spin diffusion to the crystalline region. (Adapted from Blumich et al.[56] by permission of Wiley-VCH.)

experiments. Direct evidence for the presence of an interfacial layer was obtained by monitoring the intensity of the amorphous component as a function of the spin diffusion time. Following saturation of the mobile protons with the dipolar filter pulse sequence, the intensity of the amorphous phase reached a maximum after 5 ms, indicating that there is spin diffusion between the mobile amorphous material to a less mobile amorphous material, the interface. At longer spin diffusion times (100 ms) there is extensive spin diffusion to the crystalline phase. The diffusion behavior was modeled with three components corresponding to the crystalline, amorphous, and interfacial domains. Despite the large differences in the crystallite thicknesses for the high- (40 ± 10 nm) and low-density (9 ± 2.5 nm) polyethylene, the thickness of the interfacial layer was shown to be 2.2 ± 0.5 nm in both samples.

The Goldman–Shen or the dipolar filter pulse sequences can be used to measure domain sizes via spin diffusion only when there are large differences in the spin–spin relaxation rates of the phases under study. This is often a serious limitation since the relaxation times for the crystalline, interfacial, and amorphous phases are too close to be easily separated. For this reason, other methods have been developed to create a difference in polarization between the phases. In some materials there are large differences in the proton $T_{1\rho}$s that can be used to create the polarization difference,[57] but this method is not ideal since the rate of spin diffusion is reduced only by a factor of two during the spin-lock period. A better approach is to create the difference in spin polarization using multipulse NMR methods that quench spin diffusion during the preparation period. Such methods have been used to investigate the phase structure of poly(ethylene terephthalate)[58] and polyethylene.[56]

3.3 Multiphase Polymers

Solid-state NMR is an extremely useful method for investigating the structure of phase-separated polymers. Among the key questions in such systems are how large the phases are and what the degree of phase mixing at the interface is. These questions can be investigated using the proton spin diffusion and by observing differences in the relaxation times for the material in the different phases.

Polyurethane is an example of a commercially important material that has been extensively investigated by solid-state NMR. Several polyurethanes were investigated in an early study using the Goldman–Shen pulse sequence. The magnetization recovery curve for the rigid phase of one such material is shown in Figure 32.[49] The fit to the data points is calculated for a lamellar model that accounts for some spin diffusion during the preparation period (75 μs) and is in excellent agreement with the domain sizes measured by small-angle X-ray scattering. The observation that the T_2 of the mobile phase changes

Figure 32 Recovery curve for the rigid phase in polyurethanes measured by the Goldman–Shen experiment. The solid line is a fit to a lamellar model. (Adapted with permission from Assink.[49] Copyright 1978 American Chemical Society.)

with the spin diffusion time was taken as evidence for the presence of an interfacial region.[49]

The NMR studies of polyurethanes have been used not only to measure the length scale of phase separation, but also to measure the degree to which the blocks are separated into the "hard" **(3)** or "soft" **(4)** domains. Deuterium NMR is an effective way to make such measurements because the line shapes for the material in the soft domains are much sharper than those for the hard domains, and the contributions of the hard and soft material to the deuterium wideline spectra can be easily quantified. Figure 33(a–i) show the 55 MHz deuterium NMR spectra for a series of polyurethanes containing 50, 60, and 70% hard segments that have been specifically labeled in the butanediol section of the hard segment.[59] The relative contribution of the deuterated butanediol dissolved in the hard and soft domains is obtained by subtracting the spectra for a polymer containing only the hard segments from the observed spectra, and the material with the motionally averaged line shape is assigned to the amorphous and interfacial material. The NMR results compare favorably

Hard segment

(3)

Soft segment

(4)

with those measured by small-angle X-ray scattering for the material containing 60 and 70 wt% hard segments. Similar results were reported for model polyurethanes containing deuterated piperazine rings in the hard segment and poly(tetramethylene oxide) ($M_n \approx 2000$) for the soft segment, where 85% of the labeled rings were observed in the hard domains.[60]

The structure of phase-separated diblock copolymers has been extensively investigated by spin diffusion using the Goldman–Shen[45] and dipolar filtering[51] pulse sequences. In one study the structure of a series of the poly(styrene-*b*-methylphenylsiloxane) diblock copolymers with different molecular weights, compositions, and morphologies was examined. The magnetization recovery curves for some of the samples are shown in Figure 34.[47] The spin diffusion curves for the three of the polymers show that clear differences in the morphology can be inferred from the raw data. It is well known that the morphology of block copolymers depends on the block molecular weights and compositions. It is possible to vary these parameters to obtain different morphologies for the same chemical system. The data in Figure 34 were modeled as a three-phase system, a polystyrene-rich phase, a poly(methylphenylsiloxane)-rich phase and an interface in which diffusivity changes linearly between the values of the two blocks. The dimensions of the phases and the morphologies for six samples are in close agreement with the domain sizes measured by small-angle X-ray scattering.[47]

In the experiments discussed thus far, the polarization difference between the phases is created by a difference in the relaxation times that are related to differences in the molecular dynamics. In some cases of interest, however, the differences in dynamics may not be large enough to study these materials by spin diffusion. One novel way to study such materials is the *chemical shift filter*, which selects signals for cross-polarization based on their proton chemical shift in a multipulse line-narrowing experiment.[61] This method has been used to study a series of blends, blocks, and statistical copolymers of styrene and methyl methacrylate.[62] Polystyrene and poly(methyl methacrylate) are immiscible and the block copolymers with equal block length are known to form lamellar structures. The domain sizes calculated from the spin diffusion data span a range between 0.5 and 100 nm and are in close agreement with those expected theoretically.

3.4 Polymer Blends

Solid-state NMR has been an important tool for the characterization of polymer blends and mixtures. Among the most important questions in this field to which solid-state NMR has made important contributions are what is

Figure 33 55 MHz deuterium NMR spectra of hard-segment labeled polyurethanes. Spectra (a)–(c) are for polymers containing 70, 60, and 50% hard segments, respectively. Spectra (d)–(f) show the fraction of hard segment contributing to spectra (a)–(c) and spectra (g)–(i) show the result of subtracting the hard-segment spectra from the observed spectra. the length scale of mixing in polymer blends, and what are the specific intermolecular interactions that lead to miscibility. NMR is one of the methods of choice for the determination of miscibility because the length scale measured using spin diffusion is much smaller than that inferred from differential scanning calorimetric or other studies. With the introduction of new 2D NMR methods and isotopic labeling, it is now possible to measure the local structure in polymer blends. From such studies it is possible to identify the interacting groups in miscible blends and to gain a deeper insight into the factors that determine miscibility.

The molecular level mixing of polymer chains can be investigated by measuring the chemical shifts and relaxation rates. On the smallest length scale, strong intermolecular interactions due to hydrogen bonding, charge-transfer complex formation, or ionic interactions can cause chemical shift changes that are large enough to be measured in the solid-state spectra. On a longer length scale, spin diffusion experiments can be used to measure the average distances between the polymer chains. Blend formation is also known to affect the molecular dynamics.

Most binary mixtures of polymer are not mixed on the molecular level because the entropy of mixing is extremely small for high-molecular-weight polymers, so miscibility is usually a consequence of favorable intermolecular interactions.[63] If these interactions are strong enough it is sometimes possible to observe such effects directly in the solid-state NMR spectra. One such example is shown in Figure 35(a–c), which compare the 50 MHz carbon CPMAS spectra of two polymers [**(5)** and

Figure 35 Carbon NMR spectra of (a) **(5)**, (b) a 50 : 50 blend of **(5)** and **(6)**, and (c) **(6)**. (Adapted with permission from Simmons and Natansohn.[64] Copyright 1992 American Chemical Society.)

(6)

(6)] labeled with electron-donor and -acceptor moieties in a miscible blend.[64] The miscibility is due to charge-transfer complex formation between the aromatic rings on the donor and acceptor polymers, and complex formation causes chemical shift changes from ring current effects. The largest chemical shift differences (ca. 1.2 ppm) are observed for carbons 1, 3 and 5 of the poly {[2-(3,5-dinitrobenzoyl)oxy]ethyl methacrylate} moiety.

Ionic interactions are also strong enough to influence the chemical shifts of polymers in blends,[65] as are hydrogen bonds.[66] However, unless these interactions are very strong and the peaks well resolved, only broadened lines from the interacting groups are observed.

These experiments show some cases where blend formation is driven by strong intermolecular interactions that lead to easily observable changes in the solid-state carbon NMR spectra. It is much more common, however, that blend formation is caused by weak intermolecular interactions and that the chemical shift changes induced by blend formation are smaller than the solid-state line widths, and are therefore undetectable. In such cases, the length scale of chain mixing is measured by the spin diffusion experiments discussed above.

Intermolecular cross-polarization is perhaps the most direct method to determine molecular level mixing in polymer blends. This experiment is performed on a blend of protonated and deuterated polymers, and takes advantage of the fact that the deuterated polymer has no directly bonded protons and cannot be cross-polarized. If the blends are mixed on a length scale of less than 20 Å, then the deuterated polymer can be cross-polarized from the protons on the other polymer chain.[67] This behavior is illustrated in Figure 36(a–d), which compare the cross-polarization behavior for the blend of deuterated polystyrene and protonated poly(methyl vinyl ether) with the mechanical mixture.[68] The polystyrene aromatic signals at 125 ppm are only weakly cross-polarized with a 24 ms cross-polarization time in the mechanical mixture

Figure 36 Carbon CPMAS spectra of a mechanical mixture and a blend of polystyrene-d_8 and poly(methyl vinyl ether). The data are shown for the mechanical mixture and the blend with cross-polarization times of (a) 25, (b) 10, (c) 2 and (d) 0.5 ms (Adapted from Gobbi et al.[68] by permission of John Wiley & Sons, Inc.)

while they are strongly cross-polarized in the blend. The introduction of the deuterated polymer is also a useful way to simplify the spectra of the blend when there are many overlapping signals. Since the deuterated polymer has no directly attached protons it can be observed with the nonprotonated carbons using the dipolar dephasing experiment.[69]

The length scale of polymer mixing is often measured via T_1 and $T_{1\rho}$ relaxation rate measurements.[70] If the chains are mixed on a length scale smaller than the length scale of spin diffusion, then magnetization transfer from the slower to the more rapidly relaxing chains is a very effective relaxation mechanism. In such a case the relaxation times of both chains are equal to a weighted average of the values for the individual chains and are given by Equation (26):

$$k = k_a \frac{N_a \varphi_a}{N_a + N_b} + k_b \frac{N_b \varphi_b}{N_a + N_b} \tag{26}$$

where k, k_a, and k_b are the relaxation rates (either T_1 or $T_{1\rho}$) for the blend and the pure polymers a and b, N_T, N_a, and N_b are the total number of protons and those contained in the polymers a and b, and φ_a and φ_b are the respective mole fractions. In those cases where the

length scale of mixing is longer than the spin diffusion length scale, the measured relaxation rates will be the same as for the pure polymers. In cases where there is partial mixing the relaxation behavior may be more complex, and simple exponential relaxation will not be observed.[67] One limitation of this approach to measuring polymer mixing is that the relaxation rates for the pure polymers must differ by more than a factor of two to measure accurately the averaging of the relaxation rates.

The length scale of spin diffusion L measured by such experiments depends on the relaxation time and the diffusion coefficient D, and is approximately given by Equation (27):

$$L = \sqrt{\frac{6D}{k}} \tag{27}$$

where, as above, k is the relaxation rate.[70] Assuming a diffusion coefficient of ca. $10^{-12}\,\mathrm{cm^2\,s^{-1}}$, the length scale of spin diffusion for a polymer with a proton spin–lattice relaxation time of 0.5 s corresponds to ca. 170 Å. Rotating-frame relaxation rates are typically much faster and are therefore affected by a shorter spin diffusion length scale. For a proton $T_{1\rho}$ value of 5 ms, the length scale of chain mixing that can be detected by such measurements is of the order of 17 Å. Exact measurement of the length scale of phase separation is somewhat uncertain because of the uncertainties in estimating D.

Figure 37 shows the effect of blending on the proton $T_{1\rho}$ relaxation times for poly(dimethylphenylene oxide) and poly(4-methylstyrene).[71] These polymers are ideal candidates for the study of polymer mixing because the relaxation times for the pure polymers differ from each other by an order of magnitude, so changes in the relaxation times due to the effects of blend formation can be easily measured. These data show that the relaxation rates measured for the 75:25 mixture are intermediate between those measured on the pure polymers. In addition, the rates are identical for both chains, indicating homogeneous mixing. Single exponential relaxation rates are observed for the 50:50 mixture, but the relaxation rates for the poly(4-methylstyrene) and poly(dimethylphenylene oxide) are no longer equal to each other. At a ratio of 25:75 multiexponential relaxation behavior is observed for the poly(dimethylphenylene oxide). These data show that the mixtures of poly(4-methylstyrene) and poly(dimethylphenylene oxide) are not homogeneous on the length scale measured by $T_{1\rho}$ (30 Å) for the samples prepared with a 50:50 or 25:75 ratio. This approach was initially used to study blends of polystyrene and poly(dimethylphenylene oxide), where it was reported that these polymers do not form homogeneous mixtures.[67]

Figure 37 Proton rotating-frame relaxation data for poly(2,6-dimethylphenylene oxide), poly(4-methylstyrene) and 50:50, 75:25, and 25:75 blends. The data for the 25:75 blend are offset from the other data to show the nonexponential behavior. The triangles represent measurements for carbons on poly(2,6-dimethylphenylene oxide) and the circles for poly(4-methylstyrene). (Adapted with permission from Dickinson et al.[71] Copyright 1987 American Chemical Society.)

2D proton solid-state exchange NMR has also been used to study the mixing of the polystyrene and poly(methyl vinyl ether) blends from toluene and chloroform. The broad lines in the proton spectra that result from the dipolar interactions require the use of both magic-angle spinning and multipulse decoupling during both the t_1 and t_2 periods, and the 2D exchange pulse sequence modified for solid-state proton NMR.[55] The resulting 1D spectra and the 2D correlation maps for the blends are shown in Figure 38(a) and (b).[55] Three groups of signals can be observed in the high-resolution proton NMR spectra that are assigned to the polystyrene aromatic protons at 7 ppm, the poly(methyl vinyl ether) methine and methoxy protons at 3.5 ppm, and a band containing the remaining aliphatic protons at higher field. Two sets of cross peaks are observed in the 2D spectra acquired for the blend cast from chloroform that can be assigned to the intramolecular polystyrene aromatic to aliphatic interactions and intramolecular methine/methoxy to aliphatic interactions in poly(methyl vinyl ether). In the blend cast from toluene, additional cross peaks are observed between the polystyrene

Figure 38 Solid-state proton 1D NMR spectra of a polystyrene–poly(methyl vinyl ether) (PVME) blend and the 2D spin exchange spectra for the blends from (a) chloroform and (b) toluene. (Adapted with permission from Carawatti et al.[55] Copyright 1985 American Chemical Society.)

aromatic protons and the poly(methyl vinyl ether) methine/methoxy peak. Since the only mechanism for magnetization transfer in these experiments is through-space dipolar interactions, these spectra demonstrate that a large fraction of the chains are in molecular contact.[55]

The rate of intermolecular spin diffusion and the fraction of polymer in the mixed phase for the polystyrene and poly(methyl vinyl ether) blends can in principle be calculated from the intensities of the diagonal and cross peaks as a function of mixing time.[55] A more practical way to make such measurements, however, is to use selective excitation followed by detection of the proton

Figure 39 Pulse-sequence diagram for 2D heteronuclear correlation in the solid state. Multipulse decoupling is applied to both the carbons and protons during the t_1 period and selective cross-polarization without spin diffusion occurs during the 24 pulse WIM mixing period.[75]

signals using CRAMPS.[54] These studies showed that the miscible blend was apparently nanoheterogeneous, and that 79% of the polymer was in a mixed phase. The blend has also been studied by wideline separation (WISE) NMR[72] and by the solid-state nuclear Overhauser effect (NOE).[73]

The miscibility of polymer blends has also been investigated using the 2D heteronuclear correlation experiment shown in Figure 39.[74,75] The purpose of this experiment is to correlate the carbons and protons with strong dipolar couplings. Multipulse decoupling is applied during the t_1 period to the protons and carbons with the BLEW-12 and BB-12 pulse sequences to remove both the proton–proton and carbon–proton dipolar couplings, so that the high-resolution proton spectrum can be indirectly measured.[76] Magnetization is transferred from protons to carbons with the WIM-24 pulse sequences, which quenches proton–proton spin diffusion during the cross-polarization.[74] This is in contrast to the normal cross-polarization by spin-locking, where proton spin diffusion proceeds at a half the rate observed in the absence of the rf field.[77] If a spin diffusion delay is inserted between the evolution and mixing periods, correlation via spin diffusion is observed not only between nearby protons and carbons, but also between carbon and more distant protons.

In certain favorable circumstances, it is possible to use the heteronuclear correlations to measure the geometry of the intermolecular contacts in miscible blends. Such an example is illustrated in the heteronuclear correlation spectrum of the blend of poly(vinylphenol) and poly(methyl acrylate) shown in Figure 40.[78] The strongest peaks in the spectrum arise from the correlation of the carbons with their directly bonded protons, while weaker correlations are noted between the nonprotonated carbons and nearby protons. Figure 40 shows a weak correlation between the carbonyl carbon

Figure 40 2D heteronuclear correlation spectra of the blend of poly(methyl acrylate) and poly(vinylphenol). Note the correlation between the carbonyl peak and the protons at 5 ppm. (Adapted with permission from White and Mirau.[78] Copyright 1994 American Chemical Society.)

of poly(methyl acrylate) and protons resonating at ca. 5 ppm. Since this correlation is not observed in the spectrum with a poly(vinylphenol) sample in which the hydroxyl protons have been exchanged for deuterons, this correlation must arise from the close contact between the carbonyl of poly(methyl acrylate) and the hydroxyl protons of poly(vinylphenol) due to intermolecular hydrogen bonding. Heteronuclear correlation experiments are a promising new tool to investigate the structure of polymer blends, and have been used to study polycarbonate blends with aromatic diamines,[79] polystyrene–poly(dimethylphenylene oxide)[80] and polycaprolactone–polycarbonate blends.[81]

4 THE DYNAMICS OF POLYMERS

4.1 Introduction

NMR has long been used to observe molecular motion and has been extensively applied to the complex dynamic problems presented by polymer chains. Such studies have customarily been divided into two regimes, polymer solutions, in which the chain motion is relatively fast, and polymer in the solid state, where the molecular motion is slower and may vary over many orders of magnitude. In some crystalline and glassy polymers this may reach the extreme of complete immobility. Since many synthetic polymers are useful because of their physical and mechanical properties in the solid state that are ultimately related to the molecular level dynamics, the study of the molecular dynamics of polymers has received much attention. The studies in solution primarily reveal information about *intramolecular* forces, while the molecular dynamics in the solid state are determined by the combination of *intra-* and *intermolecular* forces.

The molecular dynamics of polymers in solution are typically measured via relaxation rate measurements, such as the T_1, T_2 and NOE measurements that are most sensitive to rapid molecular motions. These same measurements are used in the solid state along with several others, including the $T_{1\rho}$, T_{CH}, and some recently developed 2D NMR methods for studying the low-frequency molecular dynamics in polymers. The choice of experiment depends to a large degree on the timescale of the polymer molecular dynamics, since each of these methods is sensitive to the dynamics over a range of correlation times. In addition, the measurement and interpretation of NMR line shapes in solids can provide additional information about both the rate and amplitude of atomic fluctuations.

Nuclear relaxation is caused by fluctuating local fields that result from the motions of nearby atoms. These fluctuations in the local magnetic fields can occur over a broad range of frequencies. If these fluctuations have components at the resonance frequency for the nuclei of interest, they will cause relaxation. The distribution of motional frequencies is given by the *spectral density function* which is defined by Equation (28):

$$J(w) = \frac{1}{2}\int_{-\infty}^{+\infty} G(\tau)\, e^{-iw\tau}\, d\tau \qquad (28)$$

where $G(\tau)$ is the autocorrelation function of the time-dependent relation expressing the orientation of the internuclear vector, such as a ^{13}C–^{1}H vector, in the laboratory frame and is given by Equation (29):

$$G(\tau) = \langle F(t)F^*(t+\tau)\rangle \qquad (29)$$

The angle brackets denote the ensemble average over a collection of nuclei and F represents a function, related to spherical harmonics, describing the position and motion of the molecule. $J(w)$ may be thought of as expressing the power available at frequency w to relax the spins in question. The spectral densities and autocorrelation functions are Fourier inverses of each other in the time and frequency domains, respectively. If $G(\tau)$ decays to zero in a short time, this corresponds to a short *correlation time* τ_c, which means that molecular motion is rapid and that the molecules have only a short memory of their previous state of motion.

In order to give these ideas specific meaning, we must adopt a dynamic model for the polymer molecule. The simplest model views it as a rigid sphere immersed in a viscous continuum that is reoriented in small diffusive

steps. The correlation time can be thought of as the interval between these alterations in the state of motion of the molecule. For such a molecule the loss of memory of the previous motional state is exponential with the time constant τ_c (Equation 30):

$$G(\tau) = e^{-(\tau/\tau_c)} \tag{30}$$

and the spectral density function becomes Equation (31):

$$J(w) = \frac{\tau_c}{1 + w^2\tau_c^2} \tag{31}$$

Figure 41 shows plots of the spectral density function as a function of frequency for three values of τ_c. A long value of τ_c corresponds to the molecular motion of a large molecule, a stiff chain, or a small molecule in a viscous medium, and a short value of τ_c corresponds to the rapid motion of a small molecule or a very flexible polymer chain. Also shown in Figure 41 is the plot for an intermediate case, when $\tau_c w_0 \approx 1$, where w_0 is the resonant frequency of the observed nuclei. The areas under the curves are the same for all three correlation times, which means that the molecular power available to cause relaxation is the same, and only the distribution varies with τ_c. For long correlation times the component at w_0 is weak, and for the short τ_c the frequency spectrum is broad so no one component, particularly that at w_0, is very intense. At some intermediate value of τ_c the intensity at w_0 with be at a maximum. Since the relaxation rate depends on the component at w_0 it will be at a maximum for the intermediate value of τ_c, and the relaxation rates will be much slower for very fast or very slow motion. The exact dependence of the relaxation rate on the correlation time will depend on which experiment is performed and which relaxation rates are measured. A critical part of measuring the molecular dynamics of polymers is choosing the proper model for the correlation functions and spectral densities. It is well established that a single exponential correlation function is not a good model for the molecular motion of an object as complex as a polymer chain.[82]

Figure 41 Plot of the spectral density functions as a function of frequency for (a) short, (b) intermediate, and (c) long correlation times. The dotted line at w_0 shows the power of the spectral density at the spectrometer frequency.

NMR studies of the chain dynamics of solid polymers utilize the relaxation measurements used for solution studies as well as several others. Solids differ from solutions in that there is not enough molecular motion to average the dipolar interactions, the chemical shift anisotropy or the quadrupolar interactions, and information about the molecular dynamics can also be extracted from the line shapes. One dramatic manifestation of this effect is the observation of the spectrum above and below the glass transition temperature, where it is often observed that the lines are sharpened above T_g by molecular motion.[83] Other types of motions that are fast on the timescale of the chemical shift anisotropy or the quadrupolar couplings, such as methyl rotation, lead to characteristic changes in the line shape. In deuterium NMR, for example, the quadrupolar line shapes resulting from aromatic ring flips or methyl group rotations can be easily recognized.[84]

More recently, 2D NMR experiments analogous to the solution 2D exchange experiments have been developed to measure the ultraslow molecular dynamics of polymers.[62] If a polymer undergoes molecular motion during the mixing time (milliseconds to seconds) then a characteristic off-diagonal ridge pattern develops in the solid-state deuterium or carbon spectra. The pattern of ridges depends both on the rate and angle of reorientation, and the molecular dynamics can be mapped out to high precision directly from the experimental data.

The methods for studying the dynamics of polymers over a wide timescale can be classified as line shape methods, relaxation rate measurements, or exchange spectra measured by 2D NMR. Each of these methods is sensitive to the dynamics over a range of timescales that depends on the type of interactions. Figure 42 shows a plot of the timescale over which each of the methods is most sensitive. The fastest motions can be measured most efficiently by the relaxation times T_1 and T_2. Motions in the intermediate timescale (10^{-7} s $> \tau_c > 10^{-3}$ s) can be measured using a variety of methods, including changes in the deuterium, dipolar, or chemical shift anisotropy line shape, the $T_{1\rho}$, or the echo intensity in deuterium

Figure 42 Plot showing the dynamics that can be measured by line shape measurements, relaxation rate measurements, and 2D exchange.

NMR. Motions in the slowest regime can be measured using 2D exchange measurements of the deuterium or chemical shift anisotropy line shape. The upper limit on the dynamics that can be studied by the 2D spin alignment or spin exchange is the T_1 of the material under study. For some crystalline polymers, this may be of the order of hundreds of seconds.

The observation of NMR line shapes, particularly those due to quadrupolar coupling in deuterated polymers or the chemical shift anisotropy in the carbon, silicon, phosphorus or nitrogen spectra, are a rich source of information about the molecular dynamics of polymers. The line shapes have a characteristic appearance in the absence of molecular motion and the changes in line shape due to the molecular dynamics depend on the type of molecular motion and the timescale over which the motion occurs. If the motion has a large amplitude and a nearly isotropic angular distribution, as for polymers above T_g, then solution-like spectra are obtained.

Deuterium NMR is often used to study polymer dynamics because the relaxation is dominated by the quadrupolar coupling, so the relaxation mechanism is well characterized.[84] Deuterium has a low sensitivity, so polymers with site-specific labels are required. This is a disadvantage in that new polymers must be synthesized, but an advantage in the sense that the labels are incorporated into the polymer at specific sites, such as the main-chain or the side-chain aromatic rings. In the absence of molecular motion, the frequency of a deuteron is given by Equation (32):

$$w = w_0 \pm \delta(3\cos^2\theta - 1 - \eta\sin^2\theta\cos 2\phi) \qquad (32)$$

where w_0 is the resonance frequency, $\delta = 3e^2qQ/8\hbar$, $e^2qQ/\hbar$ is the quadrupolar coupling constant, η is the asymmetry parameter and the orientation of the magnetic field in the principal axis of the electric field gradient tensor is specified by the angles θ and ϕ. For rigid solids $\delta/2\pi = 62.5\,\text{kHz}$ and $\eta \approx 0$ for C–D bonds. Thus, two lines are observed corresponding to the transitions for each deuteron. In isotropic samples, averaging over all possible orientations gives rise to the well known Pake spectrum.[85]

Molecular motion of the polymer will cause the line shapes to change in a way that depends on the geometry and timescale of the molecular motion. If the motion is rapid on the timescale defined by the coupling constant, $1/\delta$, it is said to be in the fast motion limit ($\tau_c < 10^{-7}\,\text{s}$). This leads to a characteristic change in line shape given by Equation (33):

$$w = w_0 \pm \bar{\delta}(3\cos^2\theta - 1 - \bar{\eta}\sin^2\theta\cos 2\phi) \qquad (33)$$

where $\bar{\delta}$ and $\bar{\eta}$ are the coupling constant and asymmetry parameter for the averaged electric field gradient tensor. It is important to note that $\bar{\eta}$ may be different from zero even though $\eta = 0$. This is illustrated in Figure 43(a–c) for kink three-bond rotation, crankshaft five-bond motion, and aromatic ring flips.[84] Such motions give rise to $\bar{\eta}$ values of 1, 0, and 0.6 and illustrate how different types of molecular motion result in characteristic deuterium line shapes.

Deuterium NMR is a powerful method for the study of the molecular dynamics of polymers, but caution must be used since it is possible for different motions to give rise to the same values for $\bar{\delta}$ and $\bar{\eta}$, and the same line shape. For example, the same $\bar{\eta} = 1$ pattern is obtained for a two-site jump model with a jump angle of 90° when the population of site two is twice that of site one, a two-site jump with equal populations and an angle of 109°, or with restricted diffusion about a tetrahedral axis with a distribution width of 70°.[86] Such models can be distinguished via the anisotropic relaxation of the line shape using the Jeener–Broekaert pulse sequence to measure T_{1Q}-distorted line shape.[86,87]

For those cases where the molecular dynamics are on the intermediate timescale, $\tau_c \approx 1/\delta$, the line shapes cannot be so easily calculated. However, information about the molecular dynamics can be obtained using echo methods. Deuterium spectra are typically very broad and cannot be acquired using the 90° pulse–acquire pulse sequences because much of the data is lost during the period after the pulse during which the electronics recover after the strong rf pulse. These data are usually acquired with the quadrupolar echo pulse sequence shown in Figure 11. If molecular motion occurs during the echo delay times, it will not be refocused and changes in the

Figure 43 Theoretical deuterium NMR line shapes for deuterons undergoing (a) kink three-bond motion, (b) crankshaft five-bond motion and (c) 180° flips, as in aromatic rings. The rate of molecular motion is assumed to be in the fast motion limit. (Adapted from Spiess[84] by permission of Springer-Verlag New York, Inc.)

line shape and intensity may be observed as a function of the echo delay time.[84]

If the motion is in the slow motion limit, $\tau_c < 10^{-4}$ s, then the line will not be sensitive to the molecular motion. If the correlation time is less than the spin–lattice relaxation time then characteristic changes in the line shape can be observed with pulse sequences that resemble the 2D exchange pulse sequence but which differ significantly in the details. As in the 2D exchange spectra, the frequencies of the deuterons in the t_1 dimension are correlated with those in the t_2 dimension. If no molecular motion occurs during the mixing time then the signals for a particular deuteron are the same in both dimensions and the signals appear along the diagonal. Thus, for mixing times that are short compared with the correlation time the normal "Pake" pattern appears along the diagonal. If the deuterons reorient during the mixing time then they have different frequencies in the t_1 and t_2 dimensions and a ridge is observed in the 2D plane that depends on the angle of reorientation. Such a ridge pattern is observed because the frequency depends on the orientation of the deuteron in the magnetic field.

The study of the molecular dynamics using the chemical shift anisotropy of carbon, nitrogen, phosphorus, or silicon is analogous to the deuterium NMR studies. The chemical shift depends on the orientation of the principal axis of the chemical tensor in the magnetic field and is given by Equation (34):

$$w = w_0 + \tfrac{1}{2}\delta(3\cos^2\theta - 1 - \eta\sin^2\theta\cos 2\phi) \qquad (34)$$

where δ is the strength of the anisotropic coupling given by $\delta = \frac{2}{3}\Delta\sigma\gamma B_0$. The chemical shift anisotropy is typically much smaller than the quadrupolar coupling with deuterium (0–4 vs 62 kHz) and therefore is sensitive to molecular motions on a different timescale.

Information about the molecular dynamics of polymers can also be obtained from the heteronuclear dipolar couplings in 1D or 2D NMR experiments. High-resolution solid-state NMR spectra are often recorded with high-power (50–100 kHz) proton decoupling and magic-angle spinning to average the dipolar interactions and the chemical shift anisotropy. However, if the molecular motion is on the same timescale as the decoupling field, interference with the decoupling will be observed and the spin–spin relaxation rate will be give by Equation (35):[88]

$$\frac{1}{T_2} = \frac{\gamma_C^2\gamma_H^2\hbar^2}{5r^6}\left(\frac{\tau_c}{1 + w_2^2\tau_c^2}\right. \qquad (35)$$

where w_2 is the decoupler field strength. When $w_2^2\tau_c^2 \approx 1$, the line width will be at a maximum and the signal will be broadened beyond detection. In a similar way, if the frequency of molecular motion is on the same scale as the magic-angle spinning, the lines will also be broadened.

The carbon and proton spin–lattice relaxation times provide gross information about the molecular dynamics of polymers, but it is frequently difficult to interpret the relaxation times in terms of the correlation times as has been effectively done for polymers in solution. It is particularly difficult for protons because proton spin diffusion is very efficient in the solid state so the measured relaxation time represents an average for the entire spin system. If the polymer contains methyl groups, then methyl group rotation is the most effective mechanism to cause relaxation and will dominate the relaxation of

the entire spin system, limiting the information about the molecular dynamics that can be extracted from such measurements. Proton T_1 measurements are very useful for studying the length scale of mixing in polymers.

NOEs can sometimes be observed for solid polymers, particularly for those near or above the glass transition temperature. Such measurements are also difficult to interpret in terms of the molecular motions because they are also mainly due to methyl group rotation.[89] These measurements are most useful for studying the structure of polymer blends and other multiphase polymer mixtures.[73]

Information about the molecular dynamics of polymers can also be obtained from the cross-polarization dynamics. As noted in section 1.2.2, the time course of the magnetization in the cross-polarization experiment represents a compromise between the buildup due to proton–carbon cross-relaxation (T_{CH}) in the spin-locking field and the decay due to carbon and proton rotating-frame relaxation rates $T_{1\rho}$(C) and $T_{1\rho}$(H).

The proton rotating-frame relaxation rates can be measured from the decay of cross-polarized magnetization or using the related pulse sequence shown in Figure 8(a) and (b). However, spin diffusion during the spin-locking pulse sequence averages the relaxation times making it difficult to relate the $T_{1\rho}$(H) relaxation times to the molecular dynamics. The $T_{1\rho}$(H) relaxation times are often very useful for measuring the length scale of phase separation in polymer blends and multiphase polymers systems.

In favorable cases, the rotating-frame carbon spin–lattice relaxation time $T_{1\rho}$(C) can be related to the molecular dynamics of polymers. The $T_{1\rho}$(C) is measured using the pulse sequence shown in Figure 8(b) in which the carbon magnetization is spin-locked for a variable contact time in the absence of the proton spin-locking field. This relaxation parameter is often of interest because the relaxation is due to molecular motions in the 15–100 kHz regime that may be related to the mechanical properties of polymers. Interpretation of the $T_{1\rho}$(C) relaxation is complicated by the possibility of cross-relaxation between the spin-locked carbons and the unlocked protons. The relative contributions of the two pathways can be estimated by measuring the relaxation time as a function of the spin-lock power, since the relaxation by the spin–spin pathway has a quadratic dependence on w_1, whereas relaxation by $T_{1\rho}$(C) has an exponential dependence. It has been reported that the relaxation in glassy polymers is primarily due by the $T_{1\rho}$(C) pathway and the relaxation times can be interpreted in terms of chain dynamics over the 15–100 kHz timescale.[90] while the relaxation in semicrystalline polymers has a substantial contribution from cross-relaxation and cannot be so easily interpreted.[91]

4.2 Semicrystalline Polymers

A variety of NMR methods, including relaxation rate measurements, deuterium NMR, and 2D NMR methods, have been used to investigate the molecular dynamics of semicrystalline polymers. Multiple signals and relaxation rates are often observed in the NMR spectra that are assigned to the crystalline, amorphous, and interfacial materials. The measurement of the molecular dynamics plays an important role in the assignment of the signals and in understanding structure–property relationships.

Polymers in the crystalline phase are in a rigid environment. Their high-resolution solid-state NMR spectra are most efficiently observed using cross-polarization and magic-angle spinning. The signals from the crystalline phase can often be distinguished from the amorphous and interfacial material by choosing a short cross-polarization contact time or in the CPT_1 experiment (Figure 6) by choosing a delay time longer than the relaxation time of the more mobile material.

Solid-state ^{2}H-NMR has been used to study the molecular dynamics of the crystalline and amorphous phases of nylon 66 **(7)** in polymers labeled with deuterium at several sites. This approach is illustrated in Figure 44, which shows the wideline deuterium spectrum at 97 °C of polymers labeled at carbons C1 and C6, C2 and C5 and C3 and C4 of the diamine moiety (NY16NHME, NY25NHME, and NY34NHME) and at the C2 and C5, and C3 and C4 positions of the adipoyl moiety (NY25COME and NY34COME).[92] These spectra show that the molecular dynamics of the various methylenes are not identical under these conditions.

The molecular dynamics of the crystalline and amorphous phases of nylon 66 can be individually measured since the differences in the dynamics of the crystalline and amorphous phases give rise to large differences in the spin–lattice relaxation rates.[93] The spectra for the labeled polymers were acquired and several models for the molecular dynamics of nylon 66 were examined to explain the temperature dependence of the line shapes.[93] The best fit was obtained for models incorporating libration motions that change in amplitude as a function of

Nylon 66

(7)

Figure 44 Fully relaxed ^{2}H-NMR spectra at 97 °C of nylon 66 polymers selectively deuterated on the diamine moiety at the C1 and C6 carbons (NY16NHME), the C2 and C5 carbons (NY25NHME) and the C3 and C4 carbons (NY34NHME), and on the adipoyl moiety at the C2 and C5 carbons (NY25COME) and the C3 and C4 carbons (NY34COME). temperature, and Figure 45 compares the experimental and simulated line shape for nylon 66 labeled with deuterium at the C_3 and C_4 positions of the adipoyl moiety along with the distribution of librational angles [$P(\Delta\theta)$] required to give a good fit between the experimental and simulated data. Further evidence for the librational model was obtained from the T_{1Q}-distorted line shape. The line shape could be modeled either with a two-site jump model or the librational model, but the T_{1Q}-distorted line shape is much closer to that expected for librational motion, even though the signal-to-noise ratio is low in these experiments.

The analysis of the deuterium relaxation for the nylon 66 polymers shows that the hydrogen-bonded NH groups act as ''pinning points'' that restrict the mobility of the nylon chains.[93,94] The mean correlation times for the ND groups varies between 200 and 500 ps over the temperature range 185–225 °C. It is also reported that above 160 °C the methylene groups in both the diamine and adipoyl moieties have similar correlation times ($\tau_c \approx$ 40 ps) that are much shorter than that for the ND groups. Below this temperature, however, the adipoyl groups experience larger amplitude fluctuations than do the methylenes in the diamine moiety. These experimental data are in close agreement with the motions observed in molecular dynamics simulations of nylon 66 crystals.[94]

The lower frequency dynamics of crystalline polymers has also been investigated by solid-state NMR using methods related to 2D exchange NMR. In such experiments the change in orientation of the atoms in the polymer chain is translated into a change in frequency during the mixing time of a 2D experiment and the frequencies before and after the motion can be directly correlated. These studies can be used to study the dynamic processes that are faster than the spin–lattice relaxation time.

Polyethylene is a semicrystalline polymer that has been extensively studied by solid-state NMR. An important feature in the relaxation spectrum of polyethylene is the so-called α transition that has been attributed to solid-state chain diffusion. It is possible to observe directly this diffusion between the crystalline and amorphous domains because their chemical shifts differ by ca. 2 ppm because of the differences in chain conformation.[14] Figure 46(a) and (b) show solid-state 2D exchange spectra obtained with magic-angle spinning that demonstrates chain diffusion between the crystalline and amorphous material.[95] These spectra clearly show the cross peaks (ca and ac) that arise from the transfer of material between the two phases. The jump rates and activation energies (105 kJ mol^{-1}) agree well with the values previously reported for the α process and show that chain diffusivities between 10^{-17} and 10^{-21} m s^{-1} can be measured by such NMR methods. These data also explain the NOEs observed for the crystalline and amorphous phases, the

nonexponential spin–lattice relaxation, and the dependence of the relaxation times on the crystallite size.

Deuteron 2D exchange NMR has been used to study the ultraslow motion in the crystalline phase of poly(vinylidene fluoride) to understand the unusual α relaxation that occurs at ca. 370 K. Figure 47 shows the experimental 2D spectra for a mixing time of 0.2 s. The best fit between the experimental and simulated spectra is obtained for a model in which there are either 67° or 113° jumps between sites in the crystalline lattice. These data are only consistent with one crystal structure of poly(vinylidene fluoride),[96] and from these data it can be concluded that chain motion is characterized by an electric dipole moment transition only along the molecular direction and by a conformational change between the $tgtg^-$ and the g^-tgt conformations. The same methods have been used to identify the 113° jumps of the monomer is the crystalline phase of isotactic polypropylene.[97]

4.3 Amorphous Polymers

Solid-state NMR has been also used to study the molecular dynamics of amorphous polymers in an attempt to gain a molecular level understanding of the relationship between the structure of polymers and their macroscopic properties. Included in these studies are the use of NMR relaxation to obtain molecular level assignments for the relaxation peaks observed in dielectric and dynamic mechanical spectroscopy and the use of these methods to understand the impact strength, gas permeability, and the other macroscopic properties of amorphous polymers.

As in the case of crystalline polymers, the molecular dynamics of glassy polymers span a range of timescales from the very rapid methyl group rotation to the very slow-motion chain diffusion. Because amorphous polymers are by their very nature disordered, the relaxation times are often nonexponential because the chains exist in a variety of molecular environments. In the previous section we saw that chain motion can often be described by a two-site jump model in the crystalline lattice. In amorphous polymers the motion is more

Figure 48 ^{13}C CPAMS of polycarbonate as a function of temperature. (Adapted with permission from Lyerla.[83] Copyright 1986 American Chemical Society.)

accurately described by a distribution of correlations times spanning several orders of magnitude.

The most rapid motions observed in polymers are the localized dynamics such as methyl group rotation that can interfere with dipolar decoupling and magic-angle spinning. Such an effect is demonstrated in Figure 48, which shows the effect of temperature on the magic-angle spinning spectra of polycarbonate.[83] At high temperature the spectrum of polycarbonate shows resolved resonances for several of the peaks, including the protonated aromatic carbons, the quaternary carbon, and the methyl carbon. Similar, but slightly broadened, spectra are observed at lower temperatures, while at intermediate temperatures the methyl signal broadens and disappears from the spectra, presumably owing to interference with the dipolar decoupling. The protonated aromatic carbons also show changes as a function of temperature. This line shape results from aromatic carbons in a variety of magnetic environments that lead to inhomogeneous broadening from conformational and ring current effects. At 295 K there is a rapid averaging among these conformations and sharp lines are observed.

The relaxation of amorphous polymers has been studied for a variety of polymers, mostly by carbon NMR, and it has been reported that the carbon T_1, $T_{1\rho}$, and T_{CH} relaxation times can be used to monitor the chain dynamics over a range of frequencies.[90] An analysis of the $T_{1\rho}$(C) relaxation in a variety of glassy polymers has shown that the relaxation is primarily due to spin–spin rather than spin–lattice relaxation. Therefore, $T_{1\rho}$(C) is a valuable probe of chain dynamics in the 10–50 kHz region while the T_1 relaxation provides information about chain motion in the 5–100 MHz regime.

The relaxation data for several glassy polymers, including poly(methyl methacrylate), polycarbonate, poly(ether sulfone), poly(2,6-dimethylphenylene oxide), polystyrene, and poly(vinyl chloride), were reported in a classical early study of the molecular dynamics by NMR.[90] The results showed both how the relaxation times provide information on the molecular dynamics and how such relaxation times can be related to important macroscopic properties. A correlation has been reported between the dynamics measured by NMR and the notched impact strength for several glassy polymers.[90]

Because of their commercial importance, the molecular dynamics of polystyrene and polycarbonate have been the focus of much attention in the polymer community. The molecular dynamics of polystyrene have been investigated by deuterium NMR for both main-chain and side-chain-labeled samples.[84] Two dynamic populations were observed for ring-labeled polystyrene on the basis of the spin–lattice relaxation studies. The line shapes for the two components can be separated using the differences in the relaxation times. Figure 49 shows the wideline deuterium spectra of atactic polystyrene-d_5 below the glass transition temperature. Using a long relaxation delay, a fully relaxed spectrum is observed that appears to have contributions both from rigid and motionally averaged materials. The line shape for the motionally averaged material can be observed with a short relaxation delay (0.05 s), and is typical of that expected for aromatic rings undergoing 180° flips. It is estimated that the correlation time for ring flipping must be of the order of 10^{-7}–10^{-8} s to give the motionally averaged spectra for the mobile material. The dynamics of polystyrene have also been studied by solid-state ^{13}C-NMR relaxation and rotational dipolar spin echo for a variety of ring- and main-chain-substituted polystyrene derivatives.[98]

These same techniques, and others, have been used to investigate the molecular dynamics of polycarbonate. Figure 50(a–d) show the wideline deuterium NMR spectra of methyl- and ring-labeled polycarbonate at 293 K.[84] The methyl deuterons give a Pake spectrum at both temperatures that can be fitted to a model containing only methyl group rotation, demonstrating that the motion of the C–CH_3 bond vector in the glassy state is in the slow-motion limit on the deuterium NMR timescale. The ^{2}H spectra for the ring-labeled polycarbonate show the characteristic line shape observed for aromatic rings undergoing 180° flips. These spectra are best described by a model in which the rings undergo

Figure 49 Experimental (a) and simulated (b) wideline ^{2}H-NMR spectra of polystyrene-d_5 with a recycle time of (a) 3 s and (b) 0.05 s at 373 K. The line shapes were simulated assuming that 20% of the polystyrene rings undergo 180° flips. (Adapted from Spiess[84] by permission of Springer-Verlag New York, Inc.)

Figure 50 Experimental [(a) and (b)] and simulated [(c) and (d)] deuterium line shapes spectra for [(a) and (c)] methyl-deuterated and [(b) and (d)] ring-deuterated polycarbonate at 293 K. (Adapted from Spiess[84] by permission of Springer-Verlag New York, Inc.)

small-amplitude oscillations in addition to the ring flips. The amplitude of the oscillations increases from ±15° at room temperature to ±35° at 380 K with a Gaussian distribution of amplitudes with a variance of 10°.

The chemical shift anisotropy line shape of polycarbonate labeled with ^{13}C at the ring position ortho to the carbonate group has been also been used to characterize the molecular dynamics of polycarbonate over a range of temperatures. Good agreement between the experimental and simulated data was obtained for models containing combinations of ring flips and restricted rotations.[99,100] These data were combined with measurements of the proton T_1 and $T_{1\rho}$ relaxation times in an attempt to relate the NMR relaxation with the relaxation peaks measured by dynamic mechanical and dielectric spectroscopy. The correlation between the data measured by NMR and other methods shows that such NMR experiments can be used to obtain a molecular level understanding of the relaxation peaks observed by other spectroscopic methods.[100] Rotational dipolar spin echo has also been used to investigate the molecular dynamics of bisphenol polycarbonate and derivatives modified on the links between the aromatic rings and for ring-substituted polycarbonates. Unlike the ^{2}H data reported for polycarbonate,[84] it was found that 20° amplitude oscillations of the methyl groups are required for the best fit of the experimental data. It is also reported that chlorine substitution on the aromatic rings quenches ring flips and substitutions at the linking groups between the rings can also inhibit chain motion.

The molecular dynamics of amorphous polymers have also been investigated as a function of carbon dioxide and hydrostatic pressure and aging. The effect of carbon dioxide on the dynamics of polymers is of interest since the molecular level processes leading to gas permeability in polymers are not well understood. The pressure of carbon dioxide (up to 35 atm) has only a small effect on the deuterium line shape of deuterated polycarbonate, polystyrene, or poly(methyl methacrylate).[101] The T_1s for polystyrene showed the greatest temperature sensitivity while polycarbonate was intermediate and poly(methyl methacrylate) showed no effect. The effect of pressure on the T_1s for polycarbonate and polystyrene can be correlated with the pressure dependence of the carbon dioxide diffusivity. These data suggest that either the polymer dynamics measured by deuterium NMR are altered by the gas, or that both the NMR parameters and the diffusivity have the same dependence of some other process, such as swelling or plasticization. Hydrostatic pressure has been shown to affect ring flips in polycarbonate[102] and polystyrene,[103] but has only a small effect on the main-chain dynamics of polystyrene.[104]

The effect of aging on the dynamics of polycarbonate and poly(ester carbonates) derived from bisphenol-A polycarbonate and tere- or iosphthalic acid has also been studied. Physical aging has little effect on bisphenol-A polycarbonate, but leads to small line shape changes in the terephthalate-labeled rings in poly(ester carbonates).[105]

Figure 51 The experimental and simulated 2D deuterium exchange spectra for chain-deuterated polystyrene at 391 K. (Adapted with permission from Kaufmann et al.[106] Copyright 1990 American Chemical Society.)

Two-dimensional wideline exchange NMR has been used to investigate the molecular dynamics of several amorphous polymers, including polystyrene, atactic polypropylene, and polyisoprene, at temperatures above T_g where the chain dynamics are in the range that can be measured by 2D NMR. Figure 51(a) and (b) show the deuterium 2D experimental and simulated 2D exchange spectra for main-chain-labeled polystyrene at 391 K, 10 K above the T_g.[106] The 2D ridge pattern from exchange is more diffuse than in the crystalline polymers, as expected for a more heterogeneous material. The key features of this pattern include extended ridges in the 2D plane at the frequency of the singularities and the decay and broadening of the center of the powder pattern along the diagonal. The pattern of cross-peak intensity in the 2D spectra as a function of mixing time and temperature cannot be described by a model with a single correlation time, but is better fitted by a model with a broad distribution of correlation times. For polystyrene at this temperature the mean correlation time is 0.006 s and the width of the distribution is 3.5 decades. The inset plot

Figure 52 Arrhenius plot of the correlation times for the main-chain dynamics of polystyrene measured by several NMR methods, including 2D exchange NMR, the solid echo, T_1 measurements and broadline NMR. (Adapted with permission from Pschorn et al.[107] Copyright 1991 American Chemical Society.)

in the simulation shows the final angular distribution of C–D bond vectors after the mixing time. Note that the differences in the simulated and experimental data at the edges of the spectra that arises from pulse imperfections.

The 2D NMR results for polystyrene can be combined with other data measured on the same polymer for a more global understanding of structure–property relationships in amorphous polymers. Figure 52 shows a plot of the correlation times for polystyrene acquired by 2D NMR, solid echo, broadline NMR and T_1 relaxation rate measurements that spans 12 orders of magnitude.[107] The data for the 2D exchange, the solid echo, and broadline NMR experiments lie on a single line that can be fitted to the Williams–Landel–Ferry equation[108] describing the temperature dependence of polymers above T_g. This shows that these data are a measure of the dynamics associated with the α transition. Conversely, the T_1 data deviate from this temperature dependence and are associated with the β transition. Similar behavior is observed for atactic polypropylene, where a single curve over many orders of magnitude was constructed from the 2D exchange data just above T_g and the spin–lattice relaxation measurements at higher temperatures.[97] Two-dimensional deuterium NMR has also been used to study the dynamics of 1,4-*cis*-polyisoprene above the glass transition temperature,[109] and multidimensional carbon and deuterium NMR have been reported for poly(methyl methacrylate)[110] and poly(ethyl methacrylate).[111]

4.4 Multiphase Polymers

Microphase-separated polymer systems, including diblock copolymers, immiscible blends, and multiblock thermoplastic elastomers, are commercially important materials that derive their function from the structure and dynamics of their phase-separated natures. These materials have been extensively studied by NMR in order to characterize the structure and dynamics of the phases and the interfaces between them. Among the important questions are how the dynamics change with temperature, how the dynamics are affected by the chemical structure of the monomers, and how the mechanical properties are related to the dynamics measured by NMR.

The structure and dynamics of polyurethanes and phase-separated segmented copolymer have been investigated by wideline deuterium NMR and magic-angle spinning cross-polarization methods. In many of these materials there is a large difference in the molecular dynamics of the segments in ''hard'' and ''soft'' domains that result in large differences in the line shapes and relaxation times. These differences have been used to characterize the length scale of phase-separation[49] and the fraction of polymer in each phase in microphase-separated polymers.[59]

The molecular dynamics of the hard segments of polyurethanes have been studied by wideline deuterium NMR in polymers site-specifically labeled at the butanediol sites in polymers based on bis(4-isocyanophenyl) methane **(8)** and 2,4-toluenediyl diisocyanate **(9)**.[112] Figure 53(a–e) show the deuterium spectra as a function of temperature and recycle delay time to separate the more rapidly and slowly relaxing components. These spectra do not show the classical Pake patterns observed for rigid polymers, but rather show a line shape consistent with a wide distribution of correlation times. Further evidence for a wide distribution of correlation times is obtained from the multiexponential spin–lattice relaxation behavior. From the studies as a function of temperature it is clear that not only are the molecular dynamics changing, but also a fraction of polymer in the hard and soft domains is changing with temperature. The line shape for the more mobile fraction can be fitted to a two-site jump model with a jump angle near 109°, corresponding to gauche–trans isomerizations, combined with small-amplitude librational motion, although this model is by no means the only one which will fit the data.

This same approach has been used to study the dynamics of the deuterium-labeled butanediol unit in poly(butylene terephthalate) and segmented copolymers containing 96 and 87% hard segments.[113] A motionally averaged line shape is observed for poly(butylene terephthalate) at room temperature that can be fitted to a two-site jump with an angle of 103° and a rate of $1.4 \times 10^5\ s^{-1}$. Similar line shapes are observed for the hard segments in the copolymers, but an additional resonance is also observed that can be assigned to mobile deuterons in the soft segments that undergo nearly isotropic motion that is rapid on the deuterium NMR timescale. These same polymers were also studied by ^{13}C static and magic-angle spinning NMR where the chemical shift anisotropy line shapes were reported.[114] These data confirm the results from the deuterium NMR studies and show that the aromatic rings in the hard segments undergo 180° ring flips.

Similar studies have been used to probe the dynamics in model polyurethane polymers containing five piperazine rings separated by carbonyloxytetramethyleneoxycarbonyl spacers. The piperazine rings are deuterium labeled at the outer (1,5), intermediate (2,4), or center position (3) to measure the dynamics at different parts of the hard segment domains.[60] As in the other polyurethanes, the line shape is a composite of the hard and soft domains. At sufficiently low temperature all motion is frozen out and a Pake spectrum is observed, whereas at high temperature all of the domains are mobile and a motionally narrowed spectrum is observed. The relative fraction of hard and soft domains depends strongly on the position of the deuterium label, with more rigid domains observed for the polymer labeled at the 3-position relative to the polymer labeled at the 2,4-positions and the 1,5-positions. Thus there appears to be a range of molecular environments for the rings in the hard segments, ranging from the most rigid at the center to the more mobile at the surface.

(8)

(9)

Figure 53 Solid-state ^{2}H-NMR spectra of deuterium-labeled polyurethanes as a function of temperature and recycle delay time. The spectra were recorded at (a) −45, (b) −2, (c) 22, (d) 55 and (e) 73 °C. The top row shows the spectra with a long delay (2–4 s), the middle row with a short delay (100–160 ms) and the bottom row is the difference. (Adapted with permission from Kintinar et al.[112] Copyright 1986 American Chemical Society.)

Further evidence for this interpretation is obtained from the temperature dependence of the line shape for the rings labeled at the three positions.

5 SUMMARY AND OUTLOOK

NMR has emerged as one of the premier methods for the analysis of polymers, and this impact can be judged in part by the many NMR articles published each year in polymer journals. As noted in the Introduction, NMR began primarily as a method for polymer analysis in solutions. The drive to understand the behavior of polymers in their native state has led to the extensive use of solid-state NMR. The solid-state NMR of polymers has benefited from continued advances in NMR methods and technologies, and in some cases these advances have been driven by the desire to better understand the properties of polymers in the solid state.

This article has reviewed many of the recent advances in solid-state NMR that make possible a detailed, atomic-level analysis of the properties of crystalline, amorphous, and rubbery polymers. NMR methods continue to evolve, and the prospects are bright for the development of new methods leading to a more quantitative analysis of polymers in the solid state. The advances will come in part from the development of new hardware that will make new experiments possible.

The solution NMR analysis of biomolecules is a sophisticated and rapidly evolving field, and many of the multidimensional NMR methods that are currently employed were developed to overcome the limitations of standard solution NMR methods. The NMR of solids is undergoing a similar evolution, and many of the experiments developed to study molecules in solutions are being adapted for studies of solids. We have seen some examples of this in this review, including 2D[115] and 3D[110] exchange NMR and the heteronuclear correlations in solids.[78]

Advances in NMR technologies will also fuel the development of new NMR methods to probe the structure of solid polymers. One exciting advance that promises to have many implications is the recent introduction of fast magic-angle sample spinning. It is now possible to buy probes that are capable of spinning samples at 35 kHz. This opens a whole new area of experiments because such spinning speeds are of the same order of magnitude as the dipolar couplings, and it may be possible to obtain high-resolution spectra of polymers from spinning alone. In favorable cases, 35 kHz spinning is fast enough to obtain high-resolution spectra without multipulse decoupling.[116,117] Proton NMR has many advantages, including high sensitivity and natural abundance, that have not been fully utilized because of the difficulty in obtaining proton NMR spectra using multipulse NMR. Fast magic-angle spinning opens up new areas for measuring the structure of polymers because proton spin diffusion can be more fully utilized to measure distances in solids. This will also make an important contribution to one of the most fundamental problems in the solid state NMR analysis of polymers, assigning the resonances. Multiple-quantum NMR with fast spinning could have an important impact on the polymer assignment problem.[116]

Recent advances in decoupling will also have an important impact on the NMR of polymers in the solid state. The combination of new probes that are able to take higher decoupling power and new decoupling schemes, such as TPPM,[8] lead to more efficient decoupling and better resolution, particularly in crystalline polymers where the dipolar couplings are strongest. Better decoupling leads to improvements in many 2D experiments where signal modulations in the indirectly detected dimensions often decay rapidly when the decoupling field is not strong enough.

The success of solution NMR for the analysis of complex materials has advanced in part because of the abundant through-bond scalar couplings that make complex magnetization transfer pathways possible. It is now becoming possible to observe these couplings in solids with new decoupling schemes,[118] such as frequency-switched Lee–Goldberg (FSLG) decoupling.[119] These advances may make it possible to transfer many of the pulse sequences used for solution analysis to the solid-state, leading to much better assignment methods.

The NMR imaging of polymers is a very rapidly evolving field that will have an important impact on the analysis of many types of polymers. To date, much of the imaging of polymers has been on elastomers, because they are easily imaged because molecular motion above T_g narrows the lines to such a degree that high-resolution images can be obtained. New pulse sequences and methods are being developed to overcome this limitation and make possible the NMR imaging of rigid solid materials.[36] The development of mobile NMR imaging systems, such as the NMR mobile universal surface explorer (MOUSE),[120] will make it possible to study a much wider variety of samples.

The advances in multidimensional solution NMR have been made possible in part by the use of pulse-field gradients for coherence selection and the suppression of unwanted resonances. These methods have recently been introduced for the study of solids with magic-angle spinning,[121] and may have a similar affect on solid-state NMR.

In addition to the advances that are driven by the development of new hardware, new methods for the analysis of NMR signals promise to increase the amount of information that we can extract from NMR experiments. One example is the new transforms being developed to analyze the signals in the rotational echo double resonance (REDOR) experiments that are used to measure distances in solids.[122] These simplify the data analysis and may make it possible to measure distances in solids routinely.

In summary, it is fair to say that solid-state NMR has an important impact on many areas of polymer science, ranging from materials characterization to understanding structure–property relationships. Given the enormous interest in NMR and polymers and the rapid growth in NMR methods and technology, the future is very bright.

ABBREVIATIONS AND ACRONYMS

CPMAS	Cross-polarization/Magic-angle Spinning

CRAMPS	Combined Rotation and Multipulse Spectroscopy
FID	Free Induction Decay
FSLG	Frequency-switched Lee–Goldberg
INADEQUATE	Incredible Natural Abundance Double Quantum Transfer Experiment
MOUSE	Mobile Universal Surface Explorer
MRI	Magnetic Resonance Imaging
*n*D	*n*-dimensional
NMR	Nuclear Magnetic Resonance
NOE	Nuclear Overhauser Effect
PVME	Polystyrene–poly(methyl vinyl ether)
REDOR	Rotational Echo Double Resonance
rf	radiofrequency
TOSS	Total Suppression of Sidebands
TPPM	Two-pulse Phase Modulation
WISE	Wideline Separation
1D	One-dimensional
2D	Two-dimensional
3D	Three-dimensional

Positron annihilation spectroscopy (PAS) is a common name for a set of techniques based on measurements and analysis of the annihilation characteristics of a positron e^+ *and its bound form with an electron* e^-*, so-called positronium* $(e^+e^-) \equiv Ps$*. PAS includes three basic techniques:*

1. *Positron annihilation lifetime spectroscopy (PALS)*
2. *Angular correlation of annihilation radiation (ACAR)*
3. *Doppler broadening spectroscopy (DBS).*

These techniques measure the time of emission, energies and momenta of positron–electron annihilation photons, respectively. PALS measures positron and positronium lifetimes and their relative intensities, giving information about the structural–physical properties of condensed materials such as metals, ceramics and polymers, while ACAR and DBS provide information about the electron momentum and energy distribution in a material. The first technique is the most developed and it serves to characterize the microstructural features of the disordered phase of condensed matter, such as defects or free-volume holes.

1 INTRODUCTION

The main goal of chemistry, physics and material science of condensed matter, especially of polymers (rubbers, thermoplastics and thermosets), is to reveal the basic structure–property relationships. For this reason, the analytical characterization of the physical structure is of fundamental importance. While analysis of the physical structure of ordered systems is the subject of classical diffraction techniques, in the case of disordered, that is amorphous polymers and nonperfect ordered (i.e. semi-crystalline), ones, PAS methods are of great importance. PAS methods are able to provide information about the physical microstructure of polymers in terms of free-volume quantities such as the mean free-volume hole size, the free-volume hole size distribution, the anisotropy of free-volume holes and the free-volume hole fraction as a function of internal variables such as chemical composition, molecular weight and crystallinity, and of external variables such as temperature, pressure and mechanical stress. In spite of this progress, however, PAS methods are continuously being developed and are close to becoming a routine analytical tool for polymer characterization. Of the above-mentioned PAS techniques, the PALS method is the most developed for microstructural characterization of disordered materials. Dimensions and timescales pertaining to existing experimental techniques for the characterization of free-volume holes, defects and voids are presented in Figure 1.

2 HISTORICAL OVERVIEW

The theoretical prediction of the positron by Dirac in 1930 and its experimental discovery by Anderson in 1932 and of positronium (Ps) by Deutsch in 1951, as well as the first application to polymers by Benedetti and Richings in 1952, led to the relatively rapid development of a new spectroscopic method for the study of the structure of matter. The initial stage in the study of the structure and properties of positron and positronium in the 1950–1960 period was followed in the 1960s by several application studies on condensed matter by physicists and in the 1970s by similar studies, this

time by physical chemists. Earlier analyses of positron annihilation spectra in terms of two components were replaced, after discovery of the third component by Tao and Green in 1965, by a more precise method in terms of standard three-term analysis. Several reviews can be mentioned.[1–3] In the case of polymers, the earliest studies were in the 1950s, continuing into the 1970s, although the information they provided was rather limited often because of the use of ill-defined polymer samples.[4,5] In the 1980s a renaissance in PAS applications in the field of polymers was connected with the accessibility of characterized polymer materials, as well as with methodological progress which consisted of raw data evaluation and subsequent interpretation allowing free-volume data quantification and its physical explanation; see various reviews.[6–12]

3 PRINCIPLES OF POSITRON ANNIHILATION SPECTROSCOPY

3.1 Positron and Positronium

The positron, e^+, is an antiparticle of the electron, e^-, with the same mass $m = 9.11 \times 10^{-31}$ kg, but with the opposite charge $e = +1.602 \times 10^{-19}$ C and with the spin $s = \frac{1}{2}$. If the positron encounters the electron, according to the Einstein formula, $E = mc^2$, the mass of the particles is converted into radiation (photons) of specific energy 0.511 MeV. Positrons are generated by the radioactive decay of certain unstable isotopes, one of the most utilized being $^{22}_{11}$Na, which decays to $^{22}_{10}$Ne with the simultaneous emission of e^+ and a γ photon of 1.28 MeV. The positrons emitted are characterized by an energy distribution between zero and 0.540 MeV, with a maximum at around 0.200 MeV. When a positron is injected into a substance it loses its kinetic energy, that is it is thermalized by a sequence of inelastic collisions with the particles of the substance. The thermalization stage for positrons occurs very rapidly, within 10 ps,[13] and is connected to the creation of excess electron-positive ion pairs along the track. The last part of this process takes place at a short distance from the thermalized positron, that is, the positron spur. Before the injected positron is annihilated by interaction with one of the electrons, it can take various physical and chemical states. Whereas, in conducting materials such as metals, positrons diffuse into the interstitial sites of perfect crystals or are trapped in vacancy-type defects in a real nonperfect crystal, in nonconducting insulating materials, such as polymers, positrons can exist in a free nonbounded state or as a bound positron–excess electron pair e^+e^-, that is positronium (Ps) with a binding energy 6.8 eV. Positronium is the lightest atom and is similar to the hydrogen atom in having the same size ($r_{Ps} = 0.53$ Å). Two ground states of Ps exist, depending on the mutual spin orientation of the positron–electron pair: singlet *para*-positronium (*p*-Ps) with antiparallel spins where the total spin of the system $S = 0$, and triplet *ortho*-positronium (*o*-Ps) with parallel spins and where $S = 1$. The corresponding formation probabilities are 25% *p*-Ps and 75% *o*-Ps, respectively.

Both the positron and positronium annihilate by emitting γ rays. The selection rule for γ photon emission is derived from the conservation laws of energy, momentum and parity considerations. Typically, two annihilation modes consist of (1) singlet ^1S annihilation for e^+ and e^-, with antiparallel spins producing two γ photons with energies of 0.511 MeV in opposite directions 180° to each other, and (2) a triplet ^3S annihilation process for parallel spin orientation, giving three γ photons with a continuous energy spectrum ranging from 0 to 0.511 MeV. In the case of Ps in a vacuum, the intrinsic annihilations of *p*-Ps and *o*-Ps are singlet or triplet annihilation

respectively, and the corresponding intrinsic lifetime of *p*-Ps is $\tau_{p-\mathrm{Ps}} = 0.125$ ns and that of *o*-Ps $\tau_{o-\mathrm{Ps}} = 142$ ns. In the condensed phase, the *p*-Ps lifetime is hardly changed by the matrix, but *o*-Ps is repelled into the regions of low-electron density, the so-called free-volume holes, where it exists for some time. Here *o*-Ps can interact with one electron of the surrounding medium which has antiparallel spin with respect to the spin of the positron in the *ortho*-positronium system. Consequently, a spin exchange or pick-off annihilation takes place, which leads to a reduction in the *o*-Ps lifetime to 0.5–5 ns by emitting two γ photons. A ''free'' nonbounded positron has a lifetime of about 0.3–0.4 ns and decays by interaction with the valence electrons of the media. Thus, a typical annihilation picture of an insulating condensed material in which *o*-Ps is formed will contain at least three components: a short-lived component from *p*-Ps with $\tau_1 \cong 0.1$–0.2 ns, an intermediate component from ''free'' positron annihilation with $\tau_2 \cong 0.3$–0.4 ns, and a long-lived component from *o*-Ps with $\tau_3 \cong 0.5$–5 ns.

3.2 Positronium Formation Models

In general, any application of PALS to determine the physical properties of polymers requires a basic understanding of the formation of Ps in polymeric materials. In positron annihilation research, three basic models of Ps formation have been formulated.

3.2.1 Ore Energy Gap Model of Ps Formation

In this model it is assumed that Ps is formed during the stage when the positron slows down and passes through a certain energy range E called the Ore gap, where e^+ can effectively pick up an electron from the molecule M to form Ps. Ps formation is represented by the energy condition: $E_i - E_{Ps} < E < E_{exc}$, where E_i is the first ionization potential of the molecule, E_{Ps} is the binding energy of Ps (6.8 eV in vacuum) and E_{exc} is the lowest electronic excitation energy of the surrounding molecules.[14] The modified version of this model[15] assumes that Ps is formed by the Ore gap process, but that Ps can undergo a set of reactions via ''hot'' Ps before it thermalizes, Equations (1–3)

$$e^{+*} + M \longrightarrow Ps^* + M^+ \quad (1)$$

$$Ps^* + M^+ \longrightarrow e^+ + M \quad (2)$$

$$e^+ + e^- \longrightarrow Ps \quad (3)$$

In polymers, the energy gap is modified by the dielectric constant, which narrows this gap, and the zero-point energy caused by Ps localization in holes, which reduces the Ps binding energy. Thus, Ps is formed in the bulk prior to localization in the hole, and Ps formation depends on the physicochemical properties of matrixes.

3.2.2 Free-volume Model of Ps Formation

In the original free-volume model,[16] Ps was assumed to be localized in an interstitial position between the lattice points which model the rigid solid matrix. In principle, this simplest version was able to explain the basic features of the temperature dependence of *o*-Ps annihilation behavior. An extended ''soft'' version of this model[17] included the effect of lattice vibrations on the annihilation process and was used to explain some temperature anomalies. These initial free-volume models have formed useful guidelines for the present understanding of Ps formation and annihilation in terms of the free-volume hole model.

According to a modern free-volume hole version of the model,[18–23] Ps is formed in an open space, a defect in the structure such as vacancy, hole or free-volume, when a positron captures an electron from the surface of the defect and subsequently Ps is trapped in this microstructural defect, Equation (4):

$$e^+ + e^-(\text{defect surface}) \longrightarrow Ps\,(\text{thermalized}) \quad (4)$$
$$\downarrow\rightarrow Ps^* + \text{defect surface} \rightarrow\uparrow$$

The probability of the positron capturing electrons from the inner surface may be energy dependent. Evidently, Ps formation will be more favorable for a positron with a lower energy than one with a higher energy. The epithermal Ps formed will continue to lose energy by collisions with the inner surface of the defects until it reaches thermalization. According to this model, the Ps formation probability is a measure of the fraction of free-volume holes, if the probability of escaping from the trapped defect to another one during its lifetime is negligible. This has been shown to be the case according to Ps diffusion data[24,25] and quantum-mechanical calculations.[26] Quantitative details will be given in section 4.4.

3.2.3 Spur Reaction Model of Ps Formation

In the spur reaction model[27] it is assumed that Ps is formed by a combination reaction of the thermalized positron and one of the excess electrons released from the molecule by the positron itself in the terminal positron spur. In this case, Ps formation must compete with other processes such as electron-ion combination, electron and positron escape from the spur, positron and electron scavenging, and so on. The Ps formation process can be expressed by the following scheme, Equation (5):

$$e^+(\text{thermalized}) + e^-(\text{spur}) \longrightarrow Ps\,(\text{thermalized}) \quad (5)$$

In a medium of static dielectric permittivity ε with thermal energy kT, a stable ion-pair is formed when the critical distance between the charged particles is $r_{cr} = e^+e^-/2\pi\varepsilon_0\varepsilon kT$, where ε_0 is the dielectric permittivity of free space. Consequently, the Ps formation probability is directly related to the spur size at the end of the positron spur.

3.2.4 Positron and Positronium Chemistry

Positron and positronium, the latter being the lightest atomic radical similar to hydrogen, can undergo various chemical interactions with specific atoms or atomic groups with large electron affinities, such as halogens, carbonyls and radicals (such as the oxygen molecule O_2) or ions, and change positron states. For example, a positron can react with an ion: $e^+ + M^- \longrightarrow [e^+M^-]$, *ortho*-positronium can undergo spin conversion: *o*-Ps + $M^\bullet \longrightarrow$ *p*-Ps + $M^\bullet$, complex formation: Ps + M $\longrightarrow$ PsM or oxidation reaction: Ps + M $\longrightarrow e^+ + M^-$. Generally, chemical reactions are transitions between different positron and positronium states, and they cause a change in the annihilation spectra (most often shortening the lifetime or the presence of additional components owing to the different properties of the positron states). In the author's opinion, the present relative autonomy of physics- and chemistry-oriented positron annihilation research will be overcome and both branches of positron annihilation research will converge, leading to a consistent and unified approach.

3.2.5 Comparison of Current Ps Formation Models

Comparing the above-mentioned models of Ps formation, we can conclude that a key difference between them consists in the positron energy at the moment of Ps formation. In the free-volume model the positron can be at both the epithermal and thermalized stage, while the Ore gap hot Ps reaction model is at the epithermal stage, and finally, the positron is mainly in the thermalized stage for the spur reaction mechanism. As for the ability to explain the maximum amount of observed experimental features, the free-volume model is able to address the problems not only of the lifetime but also of the Ps formation probability, via the relative intensity of particular positron states. On the other hand, the Ore gap model and the spur reaction concern Ps formation only. Therefore the PALS method together with the free-volume interpretation is the most developed research area in the field of PAS of polymers. For this reason, in this review we mainly focus on the principal achievements of this method in interpreting results in terms of the free-volume hole model, keeping in mind that the *o*-Ps lifetime τ_3 is determined by the free-volume hole size, while the relative intensity I_3 is dependent on both the positronium formation probability and the density of the free-volume hole sites.

4 POSITRON ANNIHILATION LIFETIME SPECTROSCOPY METHOD

4.1 Positron Source

All positron annihilation studies of polymers have been made with positron-emitting radionuclides, usually ^{22}Na in the form of ^{22}NaCl. ^{22}Na isotope emits positrons with kinetic energy up to 0.540 MeV. A typical source consists of a small spot of ^{22}NaCl prepared by evaporating the water from a droplet of ^{22}NaCl solution and sealed between two thin (usually 8 μm) special polyimide Kapton® foils. Typically, the positron strength is from a few microcurie (μCi) up to 50 μCi. This radiation level is relatively low and no special precautions are needed for protection.

4.2 Sample Preparation

The polymer to be investigated can be in any physical state, that is amorphous or semicrystalline material, the former in the glassy or rubbery state, and in any technical form: bulk, film, or powder. The sample includes two pieces of material, one placed on each side of the positron source. The most important requirement of the sample is that all positrons emitted from the source must stop and annihilate in the sample. In practice, the typical geometry of the sample is a square of 10×10 mm or a cylinder of $\Phi = 10$ mm. Since the emitted positrons have a spectrum of energies, they penetrate to various depths in the sample. In polymers these positrons can penetrate to a depth on the order of 1 mm before reaching thermal energy. For this reason, the typical thickness is 2 mm.

4.3 Data Acquisition and Evaluation

The PALS method measures the time a positron spends in the sample between injection and annihilation. The ^{22}Na isotope emits almost simultaneously (within a few picoseconds) γ photons of energy 1.28 MeV and a positron. PALS measurement is based on the detection of this γ photon, creating the start (birth) signal in one detector and, on the detection of a γ annihilation photon (0.51 MeV), giving the stop (death) signal detected by the other detector. The time difference between the two detector signals, that is the lifetime of a positron, is measured by the time-to-amplitude converter (TAC), and this information is stored in a multi-channel analyzer (MCA). Typically, as annihilation is a statistical process, 10^6–10^7 annihilation events are registered and the output

is obtained in the form of a histogram of distribution of positron annihilation lifetimes, that is the lifetime spectrum. If the positrons all annihilate in a homogeneous environment, each positron has the same annihilation probability and the lifetime spectrum consists of only one exponential. Thus, if N_0 positrons were formed at the same time $t = 0$, the number of positrons remaining at time t will be $N_0 \exp(-t/\tau)$, where τ is the mean lifetime. In the general case, when the material is heterogeneous, different positrons can have different environments and create different positron states (e^+, Ps) after they have slowed down. Consequently, if positrons and positronium are present in a sample, there are several distinct populations of positron states and the positron lifetime spectrum is a sum of several exponentially decaying components, each with its own characteristic lifetime value. In principle, two phenomenological approaches to the annihilation data analysis can be used: finite-term lifetime analysis and continuous-lifetime analysis.

In the first evaluation method, an experimental datum $Y(t)$ is expressed as a convolution (symbol *) of the spectrometer resolution function $R(t)$ and of a finite number n, usually three or more, of negative exponentials with the particular mean characteristic annihilation rate $\lambda_i = 1/\tau_i$, Equation (6)

$$Y(t) = R(t) * \quad N_t \sum_{i=1,n} \alpha_i \lambda_i \exp(-\lambda_i t) + B \qquad (6)$$

where $N(t)$ is the normalized number of counts, $I_i = \alpha_i \lambda_i$ is the relative intensity of the ith spectral component and B is the background. In practice, by fitting the model function to a measured lifetime spectrum, the values of τ_i and I_i can be extracted by using PATFIT program software.[28]

In the second evaluation method it is assumed that each component has a certain distribution of the corresponding characteristic lifetimes, so that a lifetime spectrum reads, Equation (7)

$$Y(t) = R(t) * \quad N_t \int_0^\infty \lambda \alpha(\lambda) \exp(-\lambda t)\, d\lambda + B \qquad (7)$$

in which the annihilation decay integral function is a Laplace transformation of the decay probability density function pdf $[\lambda\alpha(\lambda)]$.[29] In practice, the CONTIN[30,31] or MELT[32,33] computer programs for the numerical solution of integral equations are used.

4.4 Data Interpretation

According to quantum mechanics, the observed pick-off annihilation rate λ of positronium is given by the integral of positron $\rho^+(r)$ component of the Ps wavefunction and the density $\rho^-(r)$ of the electrons bound to the molecule at the annihilation position r in the matrix, Equation (8):

$$\lambda = \frac{1}{\tau} = \text{const} \quad \rho^+(r)\rho^-(r)\, d^3r \qquad (8)$$

At present, the solution of both the densities is an intractable problem, so that an approximated approach is used, based on a combination of a theoretical expression for a simple quantum-mechanical model of Ps confined in a hole and the existing experimental data. In this simple model, Ps is located in a spherical well with radius R_0 having an infinite potential barrier of a homogeneous electron layer with the thickness $\Delta R = R_0 - R$ inside the wall. Assuming that the annihilation rate of o-Ps inside the electron layer is $2\,ns^{-1}$ (the spin averaged annihilation rate of o-Ps and p-Ps) being close to the annihilation rate of positronium anion Ps^-,[34] the final result for the annihilation rate λ_3 of o-Ps as a function of a free-volume hole radius R_h is,[18–20] Equation (9)

$$\lambda_3 = \frac{1}{\tau_3} = 2 \quad 1 - \frac{R_h}{R_0} + \left(\frac{1}{2\pi} \quad \sin 2\pi \left(\frac{R_h}{R_0} \right. \right. \qquad (9)$$

where ΔR is the empirical parameter determined by fitting the observed lifetimes in molecular compounds, such as zeolites and molecular crystals, with the known hole and cavity sizes. The best fitted value of $\Delta R = 1.656$ Å[20] (see Figure 2). A modified free-volume model of an elliptical shape of the holes has been formulated.[35]

According to the free-volume hole model, the relative intensity of o-Ps, I_3, is proportional to the number of holes N_h in the matrix, so that the phenomenological equation for the free-volume fraction is given

Figure 2 Correlation curve between the observed o-Ps lifetimes τ_3 and the known hole sizes in molecular solids and zeolites. ○, ● molecular solids; , zeolites. (Reproduced from Jean,[9] by permission of Societa Italiana di Fisica.)

by,[21,22] Equation (10)

$$f_h(T) = K_{Vh} V_h(T) I_3(T) \quad (10)$$

where K_{Vh} is the proportionality coefficient which can be determined by various calibration procedures using other physical properties such as the macroscopic volume expansion coefficient[21,36] or by combining the macroscopic volume expansion coefficient in the liquid state above T_g with the microscopic free-volume hole fraction expansion coefficient above T_g.[37] Comparing the approaches in Refs 21 and 36, the first two are based on a direct adjustment procedure by identifying f_h from Equation (10) with the difference between the macroscopic volume expansion coefficients above and below the glass–liquid temperature T_g, while the latter makes the same adjustment via the initial temperature situated below T_g at which the dynamic free-volume holes in the liquid phase set in.

If one-to-one correspondence of the *o*-Ps lifetime and the free-volume hole radius is assumed to be valid, the lifetime distribution can be transformed into the free-volume hole radius distribution,[31] Equation (11)

$$f(R_h) = -2\Delta R_h \left\{ \cos \left(2\pi \left(\frac{R_h}{R_{0,h}} - 1 \right) \right) \right\} \frac{\alpha(\lambda_3)}{R_{0,h}^2} \quad (11)$$

The fraction of *o*-Ps annihilation in the holes with radii between R_h and $R_h + dR_h$ is $f(R_h)\,dR_h$. This assumption about one-to-one correspondence is supported by the experimental results concerning *o*-Ps diffusion in several polymers[24,25] as well as the theoretical results from quantum mechanical calculations.[26] Finally, $f(R_h)$ can be converted into a free-volume distribution function, Equation (12)

$$g(V_h) = \frac{f(R_h)}{4\pi R_h^2} \quad (12)$$

The volume fraction of free-volume holes as determined by *o*-Ps annihilation in holes with volume between V_h and $V_h + dV_h$ is $g(V_h)\,dV_h$.

4.5 Limitations

In connection with the free-volume characterization of polymers by means of the PALS method it is important to note that this technique has a dynamic character because of the existence of both intrinsic dimension and time limits. In fact, there is a lower space limit given by the smallest free-volume hole sizes detectable by *o*-Ps caused by its finite size (*o*-Ps radius is 0.53 Å) as well as a time limit connected with the timescale of molecular motions with characteristic times $\tau < 10^{-9}$ s. In addition to these basic physical aspects, chemical aspects linked to the presence or absence of the electron affine groups, which can influence the lifetime or/and relative intensity, might play the role. For these reasons, the PALS method is able to measure the *effective* free-volume microstructure determined by the mutual interplay of the above-mentioned physical and chemical factors, not the total free-volume as represented by the so-called empty free-volume $V_f^{empty}(T) = V(T) - V^w$, where $V(T)$ is the macroscopic volume and V^w is the van der Waals volume of the constituents.

5 TYPICAL APPLICATIONS OF POSITRON ANNIHILATION LIFETIME SPECTROSCOPY METHOD

In this section we present in a systematic and illustrative way the most typical applications of the PALS method in analysis of polymers. In general, there are the two basic evaluation procedures (see section 4.3) and, simultaneously, a number of internal and external variables influencing the annihilation response of polymer, such a chemical composition and molecular weight or temperature, pressure, stress, and time, respectively. In order to obtain a concise idea of the possibilities of the PALS method, we have chosen a presentation approach based on classification according to the evaluation method used and, further on, the basic external parameters, allowing for variation of the internal parameters. Thus, we demonstrate the most important effects of the *o*-Ps annihilation characteristics in rubbers and plastics, which are dependent on the basic external variables together with the revealed empirical correlations as well as important microstructural information related to various physicochemical phenomena such as transitions, relaxations and penetration phenomena.

5.1 Finite-term Lifetime Analysis

5.1.1 Thermal Effects

5.1.1.1 Amorphous Polymers The most elementary applications of the PALS method consist in investigations of the *o*-Ps annihilation data dependent on temperature T. The first results on polymers were published in Bell and Graham in 1953.

Typical courses of the *o*-Ps data, that is the *o*-Ps lifetime, τ_3, and the relative intensity, I_3, over a wide temperature range as a function of heating or cooling are shown for the illustrative case of the amorphous polymer, polyisobutylene (PIB) in Figures 3 and 4.

The first annihilation quantity, *o*-Ps lifetime, τ_3, in Figure 3 follows a generally sigmoidal course exhibiting several effects. The first pronounced effect on the relatively low temperature side is an abrupt change

Figure 3 The *o*-Ps lifetime τ_3 as a function of temperature in PIB in a heating (■) and cooling ( ) measurement regime, with the bubble model (●). (Reproduced from Krištiak et al.[38] by permission of Trans Tech Publications Ltd.)

Figure 4 The *o*-Ps relative intensity I_3 as a function of temperature in PIB in a heating (■) and cooling ( ) measurement regime. (Reproduced from Krištiak et al.[38] by permission of Trans Tech Publications Ltd.) (I_3 is a dimensionless quantity.)

of the slope at the first crossing temperature T_g^{PALS}, which lies in the vicinity of the glass–liquid temperature, T_g, from classical macroscopic thermodynamic measurements such as dilatometry T_g^{DIL} or calorimetry T_g^{DSC}. Analogous courses in the vicinity of T_g have been found for a further series of rubbers of the diene type,[38] such as 1,4-polybutadiene, (1,4-PBD) 1,4-polyisoprene (1,4-PIP) as well as for amorphous thermoplastics of very different chemical structure,[39] such as a series of polyalkylmethacrylates,[40] of polycarbonates (PCs)[41] and of epoxy thermosets.[42] For a series of diene, vinylidene and vinyl-homoatomic, backbone polymers, as well as heteroatomic backbone amorphous polymers, an empirical correlation between the τ_3 value at T_g^{DSC}, $\tau_{3,g}^{DSC}$, and the corresponding T_g^{DSC} values, the latter ranging over 300 K, has been found[43] (see Figure 5). The relationship between the mean free-volume hole size at T_g, $V_{h,g}$ and the van der Waals volume of the basic structural unit V_{mon}^{w} is useful in discussing the motional mechanism responsible for the glass–liquid transition.[43]

The second annihilation characteristic, the *o*-Ps relative intensity, I_3, exhibits a generally more complicated dependence on temperature, which is linked to both the above-mentioned dynamic and chemical aspects of the PALS method (see Figure 4). A course similar to that for PIB shows not only further elastomers such as 1,4-PIP,[44] but also thermoplastics such as PVAc,[21] PS,[45] PMMA[46] and thermosets.[42] For the amorphous elastomers cited (1,4-PIP, PIB) investigated in detail so far, the general feature is that I_3 increases with increasing temperature above the particular glass–liquid

Figure 5 The mean *o*-Ps lifetime at T_g^{DSC} vs appropriate T_g^{DSC} values for a series of 13 amorphous polymers. (1) *cis*-1,4-PBD, (2) PIB, (3) *cis*-1,4-PIP, (4) atactic-polypropylene, (5) poly n-butylmethacrylate, (6) polyvinylacetate (PVAc), (7) polyisobutylmethacrylate, (8) polyethylmethacrylate, (9) polystyrene (PS), (10) polymethylmethacrylate (PMMA), (11) bisphenol A polycarbonate, (12) bisphenol Z polycarbonate, (13) tetramethylbisphenol A polycarbon. (Reproduced from Bartoš[43] by permission of Steinkopff Verlag, Darmstadt.)

transition temperature, indicating the dominant role of increasing the number of free-volume holes in the rubbery state of amorphous polymers. In our illustrative case of PIB, an acceptable correlation between the onset temperature of the decrease in the relative intensity I_3 with the onset temperature of the so-called fast motion from the temperature dependence of the mean square displacement $\langle u^2 \rangle$ of atomic motion, as measured by using the neutron scattering (NS) method,[47] has been found. This suggests that releasing this type of microscopic mobility reduces, at least partly, the total number of free-volume hole sites at the *o*-Ps localization. In some other amorphous plastics such as PVAc,[21] PS,[45] PMMA[46] and PC,[41] more complicated courses for I_3 versus T plots have been found, sometimes with several effects, such as minima below T_g or plateau regions in the vicinity of T_g. Generally speaking, these effects might reflect the simultaneous action of physical effects such as motional degrees of freedom, and in some specific cases also chemical degrees of freedom, such as various reactions (section 3.2). For these reasons, actual interpretations of the particular polymers are currently the subject of continued intense research.

In the previous section, we mentioned the most fundamental feature of annihilation behavior of τ_3 as a function of temperature which is connected with the glass–liquid transition being dependent on the most important internal variable, that is the chemical composition of polymers. Most polymers cited were characterized by a sufficiently high molecular weight M above the so-called entanglement molecular weight M_e. In general, many physical properties of polymers depend on their molecular weight, so that some attention has been focused on revealing the influence of the second most important internal variable, molecular weight on annihilation characteristics. The most studied system has been monodisperse PS, where several research groups[48–50] found the following regularities: (1) τ_3 versus T plots exhibit a slope change at the crossing temperature $T_g^{PALS}(M)$ which grows with molecular weight M in a similar way to the calorimetric T_g^{DSC} values; (2) the lifetime at the corresponding T_g^{PALS}, $\tau_{3,g}$, is independent of M; (3) $\tau_3(T)$ below T_g^{PALS} is essentially independent of M, while $\tau_3(T)$ differs substantially, being higher for lower M at constant T above $T_g^{PALS}(M)$ as a consequence of the increase in $T_g^{PALS}(M)$; (4) at room temperature $\tau_3(300\,K)$ sharply decreases with M and is independent of M within the range $M > 10^3$, that is above the entanglement molecular weight; and finally (5) relative intensities $I_3(T)$ are higher for lower M over 20–120 °C, but all curves saturate above around 55 °C.

Phenomenologically, the low-temperature part of the sigmoidal τ_3 versus T curve around the glass–liquid transition is similar to the macroscopic volume V versus temperature T dependence from dilatometry.[51,52] However, the corresponding expansion coefficients for the macroscopic volume $\alpha_V = (1/V_g)(\Delta V/\Delta T)$ and that for the mean free-volume from Equation (9), $\alpha_{Vh} = (1/V_{h,g})(\Delta V_h/\Delta T)$, differ by one and even two orders of magnitude in the glassy $T < T_g$ or rubbery $T > T_g$ state, respectively. This is due to the fact that the former represents the global macroscopic property of both the occupied and free-volume, while the latter is a mean local property of the local regions of lowered density. Thus, the typical α_V values are about $2 \times 10^{-4}\,K^{-1}$ in the glassy state and around $5–10 \times 10^{-4}\,K^{-1}$ in the rubbery state, while α_{Vh} is an order of magnitude of $10^{-3}\,K^{-1}$ below T_g, but even an order of magnitude of $10^{-2}\,K^{-1}$ above T_g.[53] On the other hand, the microscopic free-volume hole expansion coefficient, α_{Vh}, is comparable with that for the mean square displacements $\alpha^2_{\langle u \rangle}$ of the atomic motion as detected by NS measurements, indicating the common origin of both phenomena.[53,54]

On the highest temperature side, the second dramatic change in the slope of the τ_3 versus T plot is evident at the intercept temperature $T_b \cong T_g + 150\,K$ (see Figure 2) and Jean et al.[42] and Bartoš et al.[54] Earlier, this effect was attributed to the occurrence of a specific positronium state in the soft matter – the so-called bubble positronium state.[55] It was believed[42,54] that the situation is similar to that for low-molecular weight liquids.[56] The bubble state is considered to be a result of competition between the quantum zero-point motion of *o*-Ps and the matrix resistance. The bubble size is determined by the balance between outward pressure of the zero-point motion of *o*-Ps and inward pressure from surface tension, γ, and internal pressure, p_{int}, of the medium,[56,57] Equation (13)

$$\frac{(\pi h)^2}{4m_e r_b^2} = 4\pi r_b^2 \gamma + \left(\frac{4\pi}{3} \quad r_b^3 p_{int} \right. \tag{13}$$

where m_e is the mass of the positron and r_b is the bubble radius. From application of this bubble model to our case of PIB using pVT data,[58] we can conclude that the bubble state of *o*-Ps does not appear in PIB, at least.

In addition to the two most dramatic effects in the τ_3 versus T plot mentioned above, further rather weaker effects can sometimes be found both below and above the glass–liquid transition temperature T_g.

In detailed studies of the glassy states of amorphous polymers below T_g, at some characteristic temperature(s), a slight change(s) in the slope of the τ_3 versus T plot takes place, for example in elastomers such as PIB (see Figure 3), in thermoplastics such as polycarbonate (PC),[59] PMMA[46,60] as well as in thermosets such as epoxies.[42] In some polymers, the anomalous effects are more evident via the pronounced decrease in the I_3 versus

T plot.[44–46,60,61] Within the physical framework, these empirical findings can be, from the thermodynamic point of view, related to similar effects in the corresponding $V-T$ dependences from dilatometry[52,59] and/or, from the dynamic point of view, related to the characteristic dynamic features at the microscopic and macroscopic level as detected by NS methods[47] or by the standard mechanical or dielectric relaxation techniques,[62] respectively. The relationship to microscopic dynamics is based on the observation of the temperature correlation between the subglass effect and the onset of the so-called fast motion below the corresponding T_g elastomers.[47,54] At the dynamic macroscopic level, the above-mentioned effects have been found to correlate with the presence of the so-called secondary $\beta, \gamma, \delta \ldots$ relaxations in the glassy state of polymer matrixes.[45,46,60,61]

On the higher temperature side above T_g, detailed investigations of the rubbery state of amorphous polymers have revealed a similar slight change in the slope of τ_3 versus T dependence at about 1.2–1.3 T_g. In this case, approximate agreement with the existence of the so-called liquid–liquid transition temperature T_{ll} from other experimental techniques[63] occurs (see Figure 3).

5.1.1.2 Semicrystalline Polymers According to the general free-volume idea of condensed matter, the free-volume is a measure of structural disorder and thus, it exists only in amorphous polymers or in the disordered regions of semicrystalline ones, that is, in the amorphous and interface regions and in the defect regions of the crystalline phase. In the earlier reports on semicrystalline polymers, some trends between the *o*-Ps formation probability and the degree of crystallinity have been found, but not at the quantitative correlation level, owing to various factors such as different thermal treatments, specific features connected to inhomogeneous primary and secondary crystallization, problems in crystallinity determination, and finally, ambiguity in the assignment of the positron lifetime components. Under strict control of these factors, however, using a series of polyetheretherketone (PEEK) samples as an example it has been found that (i) the *o*-Ps lifetime is independent of the degree of crystallinity x_c, (ii) the *o*-Ps intensity I_3 decreases with increasing crystallinity, and (iii) the normalized free-volume hole fraction correlates linearly with the crystallinity, giving an intercept close to 1 at $x_c = 0$.[64] These findings support the argument that all Ps annihilate at free-volume sites localized in the amorphous phase of the polymers, and indicate that the probability of Ps formation is proportional to the whole sample free-volume population in PEEK, at least. On the other hand, the detailed combined structural study of polyethyleneterephthalate (PET), by means of small-angle X-ray scattering and wide-angle X-ray scattering (SAXS, WAXS) and PALS techniques, showed that the decrease of I_3 with increasing crystallinity cannot be completely described if one assumes that *o*-Ps localizes in the amorphous phase only.[65]

It has been suggested that *o*-Ps can be formed in the crystalline regions, owing to the less homogeneous electron density of the PET crystalline lattice in contrast to the more homogeneous one in PEEK. In some other semicrystalline polymers with a relatively high degree of crystallinity, the annihilation picture appears to be more complicated. First, some researchers use four-component analysis instead of usual three-component data evaluation. Typical effects of both the long-term annihilation components on temperature are demonstrated in Figures 6 and 7 on examples of linear and branched PEs.[66]

The first two shorter lifetimes τ_1 and τ_2 reach common values and have the usual meaning (*p*-Ps and free positron), but the origin of the first of the longer components $\tau_3 \cong 0.8–1$ ns is the subject of continuing debate. It has been proposed that this additional component is connected with the existence of the e^+ or Ps molecular complex species and/or is related to the complicated morphology of the multiphase system, containing not only purely disordered amorphous phase and purely ordered crystalline phase but also the defect crystalline phase and the interface phase between the amorphous and crystalline phases. Two assignments have been proposed, but in the first case the nature of the molecular complex(es) is unknown,[67] while the other is partially supported by some relationships with the morphological features.[68] The fourth component τ_4 is comparable with that for the amorphous polymers, so that it is attributed to *o*-Ps in the free-volume holes of the amorphous regions. In addition to an abrupt change at the corresponding T_g's, the second effect is localized in the vicinity of the melting temperature, T_m, of the ordered phase.[66] Similar results from four-component analysis have been found for isotactic polypropylene (i-PP) of low and high density.[69] On the other hand, some researchers have reported three-component analysis of semicrystalline polymers such as PE, where the second component from a third-term fit is considered to be a mixture of the second and third components from a four-term fit: $\tau_2 = 0.44$ ns versus $\tau_2 = 0.3$ ns and $\tau_3 = 0.8$ ns.[70] In this case, the second component is because the temperature independence over a very wide temperature range exceeding T_m is attributed to the free positron annihilation mode.[70] Like amorphous polymers, complicated effects of the relative intensity of the longest *o*-Ps lifetime component (I_3 or I_4) versus temperature T dependence have been reported.[67–70] In

Figure 6 Positron lifetimes from fourth-component fit in linear polyethylene (PE) compared with branched PE as a function of temperature. (Reproduced from Reiter and Kindl[66] by permission of Wiley-VCH Verlag, Berlin.)

some cases, however, quite acceptable interpretations in terms of local secondary β, γ relaxations, and of global primary α relaxation connected with glass–liquid transition, have been proposed.[66,67,70]

5.1.2 Mechanical Effects

The second external variable includes mechanical action on condensed matter in the form of pressure p or of stress σ on the various types of mechanical loading of the sample, such as static uniaxial deformation or cyclic loading. The first study of positron annihilation was performed by Wilson et al. in 1963 on a series of one amorphous polymer PMMA and two semicrystalline polymers: PE and polytetrafluoroethylene (PTFE).[71] It was found that at a fixed temperature the long lifetime component decreases exponentially with the change in volume caused by increasing pressure. Further detailed studies have been carried out on amorphous epoxy thermosets under uniaxial[72] or isotropic pressure.[72,73] Generally, the increase in pressure has an opposite effect on both annihilation quantities compared to increasing temperature. It has been found

Figure 7 Relative intensities of positrons from fourth-component fit in linear PE compared with branched PE as a function of temperature. (Reproduced from Reiter and Kindl[66] by permission of Wiley-VCH Verlag, Berlin.)

that *o*-Ps lifetime and *o*-Ps relative intensity at temperatures below and above T_g decrease with increasing pressure, in the latter case more markedly than in the former one. Moreover, the pressure dependence of the mean free-volume hole size can be described by the negative exponential relationship. Similarly to the isobaric expansion coefficient of the free-volume hole size α_{Vh}, the isothermal compressibility of the mean free-volume hole size $\beta_{Vh} = -(1/V_h)(\Delta V_h/\Delta p)$ is one to two orders of magnitude higher than that of the macroscopic volume $\beta_V = -(1/V)(\Delta V/\Delta p)$. All these findings are connected to the above-mentioned fact that PALS probes only free-volume regions, while the dilatometric measurements involve both the free and occupied volume.

The deformation properties of polymers and the influence of various types of deformation on the microstructure of polymers form one of the most important topics of polymer science and technology. In a typical stress σ–strain $\varepsilon = (l - l_0)/l_0$ experiment, where l_0, l are the original and actual length of sample, several regimes of stretching behavior can be distinguished dependent on temperature and strain rate $d\varepsilon/dt$.[74] Usually, the stress

σ- versus elongation ε curve exhibits a yield point ε_y marking the boundary between elastic reversible deformation under smaller stress at $\varepsilon < \varepsilon_y$, and the inelastic irreversible one at $\varepsilon > \varepsilon_y$, which is characterized by essential structural reorganization of the material. For this reason, several PALS studies have focused on measuring these structural changes via the changes in *o*-Ps annihilation characteristics. These include both morphological types of polymer, such as amorphous PEEK,[75] PMMA,[75,76] and PC,[77,78] as well as semicrystalline PE,[79] and PTFE,[80] which have amorphous regions in the elastic state, and semicrystalline PEEK with glassy disordered regions.[81]

The first study[75] of the influence of cold tensile deformation on thermoplastics by the PALS method comes from investigation of PEEK, where a slight increase in τ_3 and a very slight decrease in I_3 have been found, the latter attributed to stress-induced crystallization in the stretched sample compared to that of the isotropic material. The anisotropy of free-volume holes has been determined by a one-dimensional ACAR method.[75] It was found that uniaxial deformation causes a change in the shape of free-volume holes from spherical to ellipsoidal in PEEK as well as in PMMA.

The preyielding regime of deformation in PC has been studied by using an in situ experimental set-up.[77] At room temperature, τ_3 grows with tensile strain up to a level of 4%, in agreement with the increase of the macroscopic volume up to 3.5% and in accord with the linear part of the stress–strain curve showing typical macroscopic yielding phenomenon at $\varepsilon_y \cong 6\%$. I_3 remains constant so that the free-volume hole fraction given by the product $V_h \cdot I_3$ increases with tensile deformation. However, the relative increase of the fractional free-volume is larger than the fractional increase in macroscopic volume, indicating that the free-volume increase is larger than that generated by an affinity expansion of the free-volume holes.[77] The detailed results of in situ study of the whole yielding regime under tension and compression in PC can be found in Xie et al.[78] The preyielding region is similar to the previous work,[78] but after crossing the yield point τ_3, I_3 decreased in such a way that the product $V_h \cdot I_3$ initially increased quite linearly, but then began to decrease at the level depending on the strain rate, being higher for a higher deformation rate. Similar results have been obtained on PMMA, but under zero-stress at the corresponding residual strain level.[76]

Semicrystalline polymers with an amorphous phase in the elastic state are discussed in Refs 4, 79 and 80. For PE,[4] a very large deformation up to a draw ratio $\lambda = l/l_0 = 12$ has influenced the lifetime spectrum only modestly, with slight decreases in τ_3 and I_3 remaining practically constant. It reflects the fact that *o*-Ps is formed in between the crystalline phase and hence the crystallite reorganization caused by deformation has no impact on the free-volume microstructure of the stretched matrix. More detailed four-component analysis[79] of hot-deformed high-density PE and draw ratios $\lambda \in \langle 1; 5 \rangle$ revealed that the two longer lifetime components are sensitive to the deformation-induced change in microstructure. Initially, τ_3, I_3 increase, and τ_4, I_4 decrease up to $\lambda \cong 2$, and at $\lambda > 3$ all parameters reach constant values. The third component has been attributed to *o*-Ps localization in the deformed paracrystalline phase, while the fourth component has been attributed to *o*-Ps localization in the increasingly ordered fibrous amorphous phase and/or in the elongated free-volume hole entities. The annihilation properties of uniaxially deformed PTFE[80] have been studied as a function of residual strain over the whole deformation range. Applying four-component fit, according to I_4 the stretching process can be divided into three stages, that is, an elastic stage, a plastic-flow region and finally, a strain-hardening regime, with the product $V_h \cdot I_3$ being constant in each stage. On the other hand, τ_4 increases with elongation in the elastic range, reaches a maximum in the plastic-flow regime, and finally tends to decrease and level off in the strain-hardening region.

The majority of free-volume interpretations of the τ_3 data have been realized by using a simple model considering a spherical shape for the free-volume hole (section 4.4). Although this approximation is plausible for isotropic materials, as confirmed by a one-dimensional ACAR experiment,[75] a nonspherical form of the free-volume holes can be expected for stretched samples. An ellipsoidal model of the free-volume hole, relating *o*-Ps lifetime to the anisotropic dimension of an ellipsoidal shape of the free-volume hole has been formulated.[35] The model predicts that the *o*-Ps lifetime in such an ellipsoidal hole will be shorter than that in a spherical one with the same volume. Application to a series of in situ uniaxially stretched semicrystalline PEEK samples with an amorphous phase in the glassy state confirmed the theoretical prediction of a large reduction of *o*-Ps lifetime at a slightly increasing *o*-Ps intensity, indicating a significant shape change after deformation. The last finding for the anisotropy of free-volume hole dimensions has been supported by the two-dimensional ACAR technique.[81]

5.1.3 Time Effects

The most important parameter in any physicochemical measurement of material properties is time, as it is an independent variable. In general, polymers are viscoelastic materials exhibiting complex temperature and time-dependent property behavior.[51,82] From the thermodynamic point of view, amorphous polymers or the amorphous phase of semicrystalline polymers

can exist in an equilibrium supercooled liquid, in the rubbery state above the glass transition temperature T_g or in the nonequilibrium glassy state below T_g. The latter is characterized by two basic phenomena: (1) formation history, that is the glassy state properties, depend on the preparation mode performed, for example, by rapid cooling (quenching) or by slow cooling of the sample, by formation pressure and so on, and (2) structural relaxation and physical ageing, that is, the evolution over time of thermodynamic properties such as macroscopic volume[51] and enthalpy, or of various mechanical and other physical properties represented by various characteristic relaxation times.[82]

One of the concepts most used to explain these often complicated formation and time dependences is based on the free-volume concept,[51,82] that is on the idea of the excess free-volume over the equilibrium free-volume level and its time evolution. For this reason, the PALS method has been often used to detect the formation history and the time evolution of the free-volume via the *o*-Ps annihilation characteristics.

On the other hand, the PALS method is characterized by two timescales. The first timescale is connected with the duration of its own annihilation process (a few nanoseconds) and the second is linked to the duration of the entire experiment, because a certain time window is necessary for data collection (several tens of minutes, up to a few hours), depending on the radiation activity of the positron source. Consequently, the final experimental response of a given material is the result of an often complicated interplay between both the intrinsic physicochemical features of the material investigated and the two above-mentioned characteristic timescales of the PALS method.

The first attempt to address the structural relaxation or physical ageing of polymers via the PALS method came from McGervey et al., using PS as an example.[83] In this and further earlier studies on amorphous polymers such as PC,[84,85] PS,[45] PVAc,[21] and PMMA,[86] as well as semicrystalline ones such as i-PP,[87] the time evolution of the *o*-Ps annihilation characteristics below T_g was believed to reflect the long-term structural relaxation, that is, that I_3 is determined by a physical factor, dominated by the density of the free-volume hole sites.

The general features of thermal cycling measurements over a wide temperature range are demonstrated for PIB in Figures 3 and 4. Two types of PALS experiment were used: one in a slow heating regime during a stepwise increase in the temperature after relatively rapid cooling down to the cryogenic temperature range, and the other one in a cooling regime during a stepwise decrease in the temperature. Two basic findings are evident: (1) the mean lifetime τ_3 is independent of the thermal cycle or the means of measurement, respectively. The constant value of the mean free-volume hole size reflects the independence of "clustering" of the constituents of the polymer matrix forming the hole defect. (2) On the other hand, the relative intensity, I_3, representing the *o*-Ps formation probability and the density of the free-volume hole sites, depends on the thermal treatment of the sample and the method of measurement. Evidently, the lower I_3 level at very low temperatures in the slowly cooled sample reflects, at least partially, the course of structural relaxation in the glassy state below T_g during the cooling procedure. Detailed studies[88–92] have revealed that the extent to which the *o*-Ps relative intensity, I_3, changes with positron exposure time, depends on the chemistry of polymer and on such external factors as the activity of the positron source and the method of annealing the sample – that is continuously together with irradiation or discontinuously outside the source. These experiments indicate the role of additional physical factors such as electric field and/or electron or positron scavenging reactions. For these reasons, in order to study structural relaxation by the PALS method, one must perform investigations under very well-defined and controlled experimental conditions that include annealing outside the measurement cell, using the same location of the sample for subsequent measurements, making a compromise between the source activity and the duration of data collection and lastly eliminating the electric charging effect by earthing the source.

5.2 Continuous Lifetime Analysis

In general, in disordered regions of polymers, the nonuniform distribution of electron density forms the heterogeneity of the local molecular environment in which annihilation takes place. Thus, the free-volume distribution is expected to generate distributions of lifetimes (sections 4.3 and 4.4). The first application of continuous lifetime analysis was carried out by Gregory in 1991, on PTFE.[93] Since then, many studies on all types of polymers, dependent on chemical structure, morphology and practically all important external variables such as temperature, pressure and mechanical stress, have been performed because of the greater information content of this sort of annihilation data analysis compared to a finite term of evaluation. These results have had a great impact, not only on polymer analytical characterization but also on the various branches of polymer chemistry and physics such as dynamics, penetration and so on.

5.2.1 Temperature Effects

The first systematic studies of the free-volume microstructure of polymers in terms of the free-volume hole radius distribution function $f(R_h)$ and the free-volume

hole distribution $g(V_h)$ and their dependence on temperature were carried out on amorphous polymers such as epoxy resin,[94] PS,[95] PC,[96] as well as on semicrystalline polymers like i-PP.[97] Following these pioneering studies, further systematic work has focused on the effects of variation in chemical structure within a certain class of polymers such as PCs[98] (at room temperature) and polyalkylmethacrylates[99] (over a wide temperature range) or on the effect of morphological change caused by phase transformation from the amorphous state to the semicrystalline state in PET.[100]

Typical results of the temperature dependence of both $f(R_h)$ and $g(V_h)$ over a wide temperature range are demonstrated by our illustrative case for PIB in Figure 8. The most important features can be summarized as follows:

1. The maxima of the $f(R_h)$ and $g(V_h)$ distribution functions shift to higher values with increasing temperature, consistent with the τ_3 results of a finite lifetime term analysis.
2. The widths of both $f(R_h)$ and $g(V_h)$ distribution functions broaden with increasing temperature; the broadening is more pronounced in the elastic state above T_g than in the glassy state below T_g.
3. Quantitatively, $f(R_h)$ distribution functions are approximately symmetric, so that they may be approximated by a Gaussian distribution function, while $g(V_h)$ distribution functions are highly asymmetric, with a pronounced tail on the high-value side, and they can be described by a log normal distribution function, Equation (14)

Figure 8 Free-volume hole distribution functions $g(V_h)$ as a function of temperature in PIB fitted by the log normal functions in Equation (14).

$$g(V_h) = \left(\frac{1}{\sqrt{2\pi w}} \quad \exp \quad \frac{-[\ln^2(V_h/V_{h,m})]}{2w^2} \right\} \qquad (14)$$

where $V_{h,m}$ and w are two basic parameters of the distribution function: the mean free-volume hole size and the standard deviation, respectively.

4. From the $f(R_h)$ and $g(V_h)$ results it follows that the R_h values are of the order of magnitude of interatomic distances, while the V_h values reach a part or a few times the occupied volume of the basic structural unit as represented by the particular van der Waals volume V^w_{mon}.

5.2.2 *Mechanical Effects*

The first analyses of the pressure dependence of $f(R_h)$ and $g(V_h)$ distribution functions on two systems studied so far, amorphous epoxy[101] and semicrystalline i-PP,[102] have revealed the following features:

1. At a given temperature the maxima of both the distribution functions shifts to lower values with increasing pressure.
2. The width of the free-volume distribution function narrows with increasing pressure.

Both these findings indicate compressing and collapsing of the free-volume holes, with a quasi-isotropic compression of the sample.

The change in the lifetime distribution with deformation has been studied on examples of hot-drawn PE.[79] The bimodal character of the distribution functions corresponding to the two long-lifetime components τ_3 and τ_4 has been found in both undeformed and deformed samples. The maximum of the longest lifetime component from the amorphous phase, shifts to lower values owing to deformation, and the width of the distribution increases slightly. The maximum of the third component increases slightly, together with an increase in the width, and was attributed to an increase in the paracrystalline disorder of the originally crystalline phase.

5.2.3 *Time Effects*

In section 5.1.3, we mentioned that the mean *o*-Ps lifetime τ_3 is independent of time for both amorphous and semicrystalline polymers. On the other hand, a special investigation of the crystallization process in PET[100] has shown that while the mean *o*-Ps lifetime τ_3 slightly increases and the relative intensity I_3 decreases with increasing degree of crystallinity x_c, the free-volume hole distribution undergoes a rather dramatic change: the maximum of $g(V_h)$ shifts to slighter higher values,

with simultaneous narrowing of the $g(V_h)$ distribution with continuing phase transformation.

6 EMPIRICAL CORRELATIONS

Many scientifically and technologically important properties like dynamic properties, that is relaxation, rheological[103] and diffusion properties,[104] have been often interpreted within the free-volume concept. In general, there are many operationally defined equations for the free-volume, $V_f(T, p)$, which can be expressed in the following unified form, Equation (15)

$$V_f(T, p) = V(T, p) - V_{occ}(T, p) \quad (15)$$

where $V(T, p)$ is the macroscopic volume from dilatometry and $V_{occ}(T, p)$ is the so-called occupied volume.[105] The latter has been postulated on a thermodynamic basis to be van der Waals volume, V^w_{mon}, giving the empty free-volume, V_f^{empty}, or the extrapolated hypothetical macroscopic volume at 0 K, V (0 K, p) providing the expansion free-volume, V_f^{exp}, and finally, in the case of semicrystalline polymers, the crystalline volume, V_{cryst} (T, p) giving a measure of structural disorder caused by phase change. Another approach based on dynamic properties consists in fitting various empirical formulae which have a free-volume interpretation, such as the Vogel–Fulcher–Tamman–Hesse (VFTH) equation for viscosity or relaxation time data or, equivalently, the Williams–Landel–Ferry (WLF) equation for the shift factor results. Although the free-volume concept has been successfully used in correlating and explaining many physical quantities such as viscosity, relaxation time, correlation time and diffusion coefficient, this success was achieved at the expense of the existence of many different free-volume definitions. On the other hand, the present progress in direct measurement of the *effective* free-volume properties by the PALS method opens up a unique opportunity to directly relate the corresponding microstructure free-volume properties to the relevant dynamic and diffusion properties. Several empirical correlations of this kind will be presented.

In the case of dynamic properties of polymer liquids, an empirical correlation between the expansivity of the mean free-volume hole $\beta_h = \Delta V_h/\Delta T$ and the fragility m_g, as well as the nonexponentiality β_g, has been found for a series of seven polymers.[106] The fragility m_g is a measure of the non-Arrhenius character of the temperature dependence of viscosity or relaxation time, and the nonexponentiality coefficient β_g is a measure of the non-Debye time behavior of relaxation time. These correlations indicate a close relationship between the presence of the free-volume holes detectable by PALS and the basic dynamic temperature and time features of polymer liquids. Consequently, a direct empirical correlation between the effective free-volume data and the viscosity data in PIB via the WLF–Doolittle type equation has been established.[107]

In the case of diffusion behavior of small gas molecules in polymer matrices, several correlative studies have been presented.[98,108–111] The first systematic study of the mutual relationship between these characteristics was performed for diffusion of carbon dioxide and methane in nine rubbery polymers at temperatures from T_g up to $T_g + 70$ K.[108] The free-volume Fujita–Doolittle[112] model for diffusion was tested and it was found that a correlation between the diffusion coefficient D and the mean free-volume hole size V_h is better than that between the D values and the product $V_h \cdot I_3$. In a following work, the same authors studied the relationship between sorption behavior and annihilation characteristics in a series of polyimides in the glassy state below T_g.[109] In a further work,[110] an empirical correlation between the expansion free-volume V_f^{exp} and the free-volume hole size V_h at room temperature was revealed. Consequently, acceptable correlations between the mean free-volume hole sizes V_h in polymer matrices and the corresponding diffusion coefficients for a variety of gases, such as argon, nitrogen and oxygen, in a series of seven polymers with very different chemical structures have been presented via the Fujita–Doolittle-type expression. On the other hand, a correlation between the empty free-volume fraction and the measured free-volume hole fraction has been found for a series of four PCs.[98] Consequently, a number of free-volume correlations for the diffusion coefficients of oxygen and carbon dioxide in these materials have been presented. Finally, similar relationships between the permeability coefficient P, the product of the *o*-Ps lifetime and the relative intensity for carbon dioxide and methane in a series of seven polyetherimides have been found.[111]

ACKNOWLEDGMENTS

The author wishes to thank Drs J. Krištiak, O. Šauša, P. Bandžuch, K. Krištiaková and J.Zrubcová for their very close collaboration and enthusiasm during our investigations of polymeric materials, as well as to the Slovak Grant Agency VEGA for supporting this research with grant 2/4008/97.

Pyrolysis is defined as a chemical degradation reaction induced by thermal energy only,[1] and analytical pyrolysis is the study of materials based on the results of such reactions. Since the overall result of a pyrolysis reaction is the production of small molecules from larger ones, it is extensively utilized in the analysis of polymers, especially as a sample introduction tool since it permits the application of techniques such as gas chromatography (GC) to such macromolecules by breaking them into fragments which are compatible with the technique. Interpretation of the results of a pyrolytic analysis depend on an understanding of the degradation mechanisms involved, which reflect relative bond strengths within the macromolecule. Since specific polymers are chemically different from each other, the degradation products they make are different, providing characteristic information about the original macromolecule. Analytical pyrolysis, coupled with GC, mass spectrometry (MS), gas chromatography/mass spectrometry (GC/MS), Fourier transform infrared (FTIR) spectroscopy and other techniques, has been used in the study of a wide range of polymer types, including polyolefins, vinyl polymers, polyurethanes, acrylics, rubbers, polyamides and polyesters.

Analytical laboratories employ one of a variety of pyrolysis techniques (microfurnace, resistively or inductively heated filament) interfaced to a detection instrument (GC, MS, FTIR) to create an analytical system. These combined systems have strengths and weaknesses based on the limitations of the individual components and must be optimized for a particular analysis. Systems have been devised which permit the routine analysis of such difficult materials as cured and cross-linked paints and rubbers, textile fibers, filled composites, laminates, dried adhesives, copolymer systems, coatings and packaging. Practical applications are found in laboratories charged with the analysis of forensic evidence, museum artifacts, ink, paper, lubricants, automobile tires, clothing, varnish, wood products, furniture and food containers.

1 INTRODUCTION

Because so much of the chemistry observed in pyrolysis reactions involves free-radical reactions, the early history of pyrolysis largely parallels the development of free-radical theory. What is considered by many to be the first intentional application of pyrolysis for an analytical purpose, however, was the analysis of natural rubber by Williams[2] in 1862, well predating the development of free-radical theories. By heating a sample of rubber (polyisoprene) to the point of destruction, Williams produced both the monomer and dimer of the polymer. Free-radical mechanism theories developed in the early years of the 20th century, and the relationship between pyrolytic processes and free-radical generation was shown in 1929 in the well-known experiments by Paneth and Lautsch.[3] This work demonstrated that, first for tetramethyllead and then for tetraethyllead, high temperatures produced elemental lead and alkyl free radicals, which could subsequently react with a second source of the metal. By 1931, in referring to the work of Paneth, Rice[4] stated that, ''We can proceed

Encyclopedia of Analytical Chemistry
R.A. Meyers (Ed.) Copyright © John Wiley & Sons Ltd

with some confidence to examine the mechanism of the decomposition of organic compounds from this point of view because the actual existence of the simple alkyl radicals has now been demonstrated''. Rice then went on to publish widely concerning free-radical degradation mechanisms experienced by organic molecules at high temperatures, including products from paraffins[5] and chain reaction mechanisms.[6] The evolution of early pyrolysis applications has been reported in some detail by Irwin, first in a 1979 review article[7] and later in a text[8] on analytical pyrolysis.

From an analytical standpoint, pyrolysis must be coupled with some other device for the identification of the products made, and by far the most common is GC. Analysts realized early on in the development of GC that pyrolysis/gas chromatography (Py/GC) provided a means of analyzing materials not suitable for GC in their native state. As early as 1962,[9] pyrolysis had been coupled to GC for the analysis of hydrocarbons, which led Dietz[10] to comment that the results suggested that, ''many different types of organic substances can be characterized by pyrolysis techniques.'' By the early 1970s Py/GC was already being applied to the analysis of such complex problems as the microstructure of ethylene–propylene copolymers[11] and monomer inversion in polypropylene.[12] A review by Brauer[13] in 1970 listed 200 references to polymer characterization using Py/GC, including qualitative analysis, quantitative estimation of copolymer composition and studies on thermal stability. In subsequent years, applications continued to grow, with the introduction of commercial instruments for pyrolysis, and the publication of additional texts on pyrolysis[14,15] and review articles.[16–18]

2 CHEMISTRY: DEGRADATION MECHANISMS

A considerable amount of work has been published on the degradation mechanisms experienced by polymers when heated to pyrolysis temperatures. This includes general reviews of mechanisms[19,20] and also studies into the degradation of specific polymers, including polybutadiene,[21] polystyrene,[22] polyesters,[23] polyurethanes[24] and fluoropolymers.[25]

Although any particular material may be studied for years in an effort to arrive at a definitive understanding of the degradation processes experienced during its pyrolysis, some fairly simple generalities may be proposed for an overall appreciation of the chemistry involved. Degradation mechanisms are frequently grouped into four categories, i.e. random scission, in which a polymer dissociates at multiple points along the chain to produce a variety of oligomeric products, unzipping, which causes the polymer to revert to monomer, side-group scission, which eliminates groups attached to the polymer chain, and char formation, which results in a complex nonvolatile residue. From the standpoint of analytical pyrolysis, which usually deals only with the volatile products of pyrolysis, the problem may be reduced to just two broad categories based on a simple model of bond types.

Many synthetic polymers may be seen to be variations of the simple model **(1)**, in which there is a long carbon chain (—C–C—) attached to which are side-groups, shown here as a, b, d and e. To make up the polymer, this simple unit is repeated many times, and different polymers are created by changing the identity of the side groups. For example, if all groups a–e are hydrogen atoms, the polymer is polyethylene. If a, b and d are hydrogen and e is a methyl group, the polymer is polypropylene. If e is Cl, the polymer is poly(vinyl chloride) (PVC), if both b and e are Cl, the polymer is poly(vinylidine chloride), and so on. Seen this way, there are just two kinds of bonds to be concerned with – those which hold the chain together (C–C) and those which

(1)

attach the side groups (C–a, C–b, C–d and C–e). Since pyrolysis is defined as a degradation mechanism induced by thermal energy only, bond dissociation is the principle pathway to the generation of products. As the polymer molecule is heated to pyrolysis temperature, the weakest bonds break first, and these bond dissociations will dictate most of what is seen as product. Consequently, two very broad degradation mechanisms arise. First are cases in which the C–C bonds holding the chain together are the weakest, and second are cases in which bonds attaching a side group are weaker than the C–C bonds of the chain.

2.1 Chain Bonds are Weakest

If the bonds holding the side groups to the chain are stronger than the bonds holding the polymer chain together, pyrolysis causes chain scission, producing fragments of the polymer with the side groups intact. This bond dissociation produces two free radicals, and the products which result from the pyrolysis depend on the nature and structure of these free radicals. Polyethylene, for example, dissociates to form two primary free radicals as shown in Scheme 1, which may then undergo any processes normal for free radicals, including β-scission, hydrogen transfers and so on. Immediate β-scission will

Scheme 1

produce a molecule of ethylene, the monomer, and regenerate the free radical on the chain.

Transfer of a hydrogen from the next carbon, followed by β-scission, will produce a molecule of propylene. The free-radical may abstract a hydrogen from a neighboring molecule and simply become a saturated chain end. A hydrogen may be transferred from the fifth carbon in the free radical, via a six-membered ring, to produce the secondary free radical shown in Scheme 2.

Scheme 2

This 1–5 hydrogen transfer is an important mechanism in understanding the product distribution in the pyrolyzate of many polymers. By transferring the hydrogen to the first position, a secondary, more stable free radical is formed at the fifth carbon. When this free radical undergoes β-scission, 1-hexene is formed, which is the trimer of ethylene, and the free radical continues on the chain of the polymer. It is important to recognize that the three monomer units which are eliminated together as the trimer are connected to each other in the same way that they were in the original polymer, and such oligomeric fragments therefore convey much microstructural information.

Since all of the carbon–carbon bonds along the chain have the same bond strength, at pyrolysis temperatures any of them could dissociate. Two dissociations near each other will produce an oligomeric fragment which may be small enough to be analytically significant. Since the free radical may take a hydrogen from a neighboring molecule, creating a chain ending in CH_3, eliminate a hydrogen or undergo β-scission, producing a chain ending in $C{=}CH_2$, the resulting hydrocarbons could have no double bonds, a double bond at one end or double bonds at both ends. Consequently, the pyrolyzate generated from polyethylene consists of chain fragments which are normal hydrocarbons, a mixture of alkanes, alkenes and dienes. All of these processes are evident in a pyrolysis chromatogram (pyrogram) of polyethylene, such as that shown in Figure 1. The triplets of peaks represent the diene, alkene and alkane of increasing chain length, with the C_{12} hydrocarbons eluting at about 14 min. The 1–5 hydrogen transfer accounts for the increased amount of hexene (at 2 min) over the amounts of pentene or heptene, eluting just before and after it. Since the hydrogen transfer may take place more than once, there is an increased amount of the pentamer (decene) and the heptamer (tetradecene) in addition to the trimer, so the pattern always shows larger peaks for the C_6, C_{10} and C_{14} hydrocarbons. The fact that all normal hydrocarbons up to C_{30} are represented indicates that the chain bonds are all equally likely to dissociate.

The presence of side groups other than hydrogen significantly affects product formation, even in cases where the chain-length bonds are the weakest. Poly(methyl methacrylate) (PMMA), for example, undergoes bond dissociation to produce structure **(2)**.

(2)

Unlike polyethylene, this is already a tertiary free radical, so internal rearrangements such as hydrogen transfers cannot produce a more stable species. Further, the carbon fifth from the end is not bonded to a hydrogen, so the 1–5 hydrogen transfer mechanism is impossible. As a result, the free radical simply undergoes β-scission, which produces a molecule of methyl methacrylate (MMA) monomer and regenerates the free radical on the polymer chain. This process continues almost to the exclusion of any other reaction, and the end result is essentially regeneration of the monomer. Consequently, the pyrogram produced from PMMA is very simple, showing little more than a single peak for the MMA monomer, as shown in Figure 2. In polymers where there is a hydrogen available for a 1–5 transfer, this mechanism usually occurs, resulting in the generation of trimer.[26] Poly(methyl acrylate), then, does produce methylacrylate trimer whereas PMMA does not, polystyrene does, but poly(α-methylstyrene) does not, and so on.

2.2 Side Bonds are Weakest

If the bond attaching a side group to the polymer chain is weaker than the bonds of the chain itself, the side group will be removed from the polymer before the

Figure 1 Pyrolysis of polyethylene, showing triplet *n*-hydrocarbon peaks.

chain breaks apart. Consequently, the monomer identity of the polymer is altered and no monomer appears in the pyrolyzate, whereas some monomer is almost always present if the chain-length bonds are the weakest. The absence of monomer does not hinder the ability to identify the polymer from the pyrolyzate, however, since the pyrolysis products are as characteristic and reproducible for this kind of polymer as for any other. PVC, for example, does not produce vinyl chloride monomer when it is pyrolyzed, because the C–Cl bond is weaker than the C–C bond of the chain. At relatively low temperatures (below 400 °C) the C–Cl bond dissociates, making a Cl free radical. This Cl free radical quickly picks up hydrogen from a neighboring carbon and forms HCl, leaving the polymer chain unsaturated. As the polymer is heated further, the unsaturated chain breaks apart, generating aromatics, including benzene, toluene and naphthalene. The combination of aromatics and HCl in a pyrolyzate (see Figure 13, described in section 5.5) is always characteristic of PVC. Poly(vinyl acetate) (PVA) degrades in a similar way, producing acetic acid plus aromatics, and a copolymer of PVA and PVC will produce aromatics plus both HCl and acetic acid.

Poly(vinylidene chloride) (PVDC) provides a good example of how relative bond strengths are reflected directly in the pyrolyzate. In the original polymer, the C–Cl bonds are weaker than the C–C bonds of the chain, so it too releases HCl, as shown in Scheme 3, leaving a chlorinated, unsaturated backbone of the polymer.

Scheme 3

The resulting material now contains C=C–Cl bonds, which are stronger than the C–Cl bond in the original polymer. Upon further heating, the backbone dissociates and cyclizes, forming aromatics, but the chlorines are retained, so the principal product is 1,3,5-trichlorobenzene. PVC then produces a variety of unchlorinated aromatics, PVDC generates chlorinated aromatics, but neither makes monomer.

Figure 2 Pyrogram of PMMA. The largest peak is the monomer (MMA).

2.3 Elimination of Small Molecules

In addition to the degradations outlined above, some polymers produce simple gases as they are pyrolyzed, especially polymers including atoms other than carbon and hydrogen. Cellulose and cellulose-based materials including paper, cotton, rayon and cellophane produce considerable CO, CO_2 and water at pyrolysis temperatures[27] in addition to levoglucosan, furans and other oxygen-containing compounds. Ohtani et al.[28] have outlined a scheme accounting for the mono- and dinitriles formed in the pyrolysis of nylons in which the nitriles are formed from the polyamide via a dehydration step. Lytle et al.[29] reported the production of water, HCN and CO as products in the pyrolysis of phenolic urethanes. The products observed in the pyrolysis of polyesters[23] are formed by processes involving considerable decarboxylation.

2.4 Microstructure

Because the fragments generated from pyrolyzing a polymer retain structural information from the original macromolecule, studying these fragments provides considerable information about the nature of the polymer. This is even true regarding the arrangement of the monomeric units in the polymer, revealing structural details such as monomer inversion, tacticity and especially the difference between random and block copolymers. This is a direct result of the fact that differing arrangements of monomers along a chain produce chemically different materials, and these differences survive the pyrolysis event. In a homopolymer, for example, monomers which generally align themselves in a head-to-tail arrangement may form head-to-head or tail-to-tail bonds, which are analytically discernible. In the case of PVC,[30,31] for example, an inversion of this type would result in a structure such as **(3)**, instead of one in which the chlorines are attached to alternate carbons. The effect of having chlorines on neighboring carbons is the production of chlorinated aromatics, particularly chlorobenzene. Likewise for polypropylene,[32] tail-to-tail bonding would place two methyl groups an additional carbon apart, and consequently produce structures which are 2,5-dimethyl instead of 2,4-dimethyl substituted. In addition for polypropylene, since the polymer chain, which is frequently drawn as shown in structure **(4)**, contains asymmetric carbons, there are issues of stereoregularity. The relative positioning of the methyl groups on these asymmetric carbons in the polymer chain dictate the relative

(3)

(4)

amounts of various specific degradation products, and this information is reflected in the pyrogram. Figure 3 shows a pyrogram of isotactic polypropylene and Figure 4 shows atactic polypropylene for comparison.

These considerations take on an additional significance in the case of copolymers. Because oligomers formed by pyrolysis, especially trimers and larger, show the positions of monomeric units as they were in the polymer, significant microstructural information about the copolymer is provided. If a copolymeric material is a block copolymer, or a blend of polymers, there are large sections of homopolymer in the system and the oligomeric fragments will be made of only one monomer. If the system is a random copolymer in which two or more monomers are joined together in the same polymer molecule, the oligomeric fragments will show a random mix of monomers, in addition to the homogeneous oligomers. An example of this may be seen in polyethylene–polypropylene copolymers. If the copolymer is a block copolymer, there are sections of polyethylene and sections of polypropylene. When the sample is pyrolyzed, the oligomers seen in the analysis, containing for example 3–10 monomeric units, will be the same as those seen in the pyrolysis of a homopolymer. Figure 1 shows a pyrogram of polyethylene and Figure 3 shows polypropylene, each revealing a repeating pattern of oligomeric peaks, but different from each other. A pyrogram of a block copolymer will look like Figure 1 superimposed on Figure 3, since all the oligomers of both polyethylene and polypropylene are present. The relative amounts of the two sets of oligomers depend directly on the relative amounts of the two monomers used. Figure 5 is a pyrogram of an ethylene (25%)–propylene block copolymer, in which oligomers seen in both Figures 1 and 3

Figure 3 Pyrolysis of isotactic polypropylene.

Figure 4 Pyrogram of atactic polypropylene.

Figure 5 Pyrogram of ethylene–propylene block copolymer.

may be seen. Since the sample is 75% polypropylene, it looks more like Figure 3, and the trimer, tetramer and pentamer of propylene have been marked 3, 4 and 5 respectively. Nevertheless, the triplet normal hydrocarbon peaks from polyethylene are clearly seen throughout the chromatogram, especially after 20 min where they can be seen eluting between the larger propylene oligomers. Three of the polyethylene oligomers have been marked with asterisks to help identify them.

Ethylene–propylene rubber, however, is a random copolymer, so the oligomeric fragments will contain both ethylene and propylene monomers, in a wide and random array of positioning. Consequently, the pyrogram produced from the rubber will look nothing like that from the homopolymers or from the block copolymer. Figure 6 shows a pyrogram for ethylene–propylene rubber, demonstrating the large number of peaks detected at each chain length, because of the varied number and position of the methyl groups introduced by the propylene monomer.

All of this can be seen more easily by expanding the chromatograms of the different homopolymers and copolymers discussed above. In Figure 7(a–d) the region between 20 and 30 min for each pyrogram is represented. Pyrogram (a) shows just polypropylene, and the two sets of oligomers in this region are the hexamers and heptamers of propylene (containing 18–21 carbons). Pyrogram (c) is just polyethylene, and the normal hydrocarbons shown contain 15, 16, 17, 18 and 19 carbons. Again, the triplets arise as the diene, alkene and alkane of each carbon number, eluting in that order. Between these two pyrograms is the analysis for the block copolymer, pyrogram (b). This pyrogram shows the hexamers and heptamers of polypropylene, and also the normal hydrocarbons from polyethylene (the C_{17} and C_{19} triplets are the easiest to see). From this region, then, it is clear that at least seven propylene units must have been adjacent to each other in the original polymer, and at least 10 ethylene units, but, referring to Figure 5, shows evidence of considerably longer sections. Pyrogram (d) is from the random copolymer, showing at least 10 different oligomers for each carbon number and many peaks from mixed oligomeric fragments which are clearly absent from the pyrograms of the homopolymers and the block copolymer.

3 INSTRUMENTATION

Although pyrolysis equipment has been designed with a capacity to handle very large samples, for applications such as recycling scrap polymers, analytical utility generally depends on the ability to heat a small sample very rapidly, generally to a relatively high temperature. This is particularly true for GC interfacing, since the pyrolysis constitutes sample introduction. Slow heating or pyrolysis at low temperatures would introduce the sample in a broad band, not compatible with good chromatography. Consequently, most product development has centered around devising a means to heat a sample very rapidly but still maintain control of the heating

Figure 6 Pyrogram of ethylene–propylene rubber (random copolymer).

rate, temperature and time. Most commercially available instruments achieve this by one of three means: inductive heating, resistive heating or constant (isothermal) heating. Some applications require the ability to heat at slow rates, however, and adaptations of standard instruments supply this capability.

3.1 Constant Heating: Isothermal Microfurnaces

One of the easiest and least expensive ways to heat a sample to a preset temperature is to introduce it into a zone which is already heated to that temperature. The heating rate of the sample then is just the rate at which

Figure 7 Expanded pyrogram sections for (a) polypropylene, (b) block copolymer, (c) polyethylene and (d) ethylene–propylene rubber.

Figure 7 (*Continued*)

the material heats to the new ambient temperature, which is in part dependent on the sample material and mass. Most commercially available microfurnaces are capable of heating the pyrolysis zone to 800–900 °C, which is more than enough to pyrolyze most polymers. Among the advantages of microfurnaces are the relatively low cost, simplicity, stability and ease of use. Disadvantages include a relatively large heated surface area which promotes secondary pyrolysis reactions and difficulty in introducing some types of samples conveniently. Some furnaces permit sample introduction through a septum port only, which means that the sample must be capable of being delivered by a syringe, or plunger-type solids syringe.[33] Other designs incorporate a cooled zone with a sample basket which may be lowered into the heated zone for pyrolysis.

3.2 Inductive Heating: Curie Point

A second way to heat a sample rapidly is to place it on a cool material which may be brought to an elevated temperature quickly. Curie point pyrolyzers are based on the principle that a current may be induced into a ferromagnetic material by use of a high frequency coil. The ferromagnetic metal will be heated rapidly by the current induced in it, until it reaches a temperature at which it is no longer ferromagnetic. At this point, the Curie point for that metal, the heating stops and the temperature stabilizes. The Curie point is different for each ferromagnetic metal or alloy of those metals, so by creating different alloys of iron, cobalt and nickel a range of temperatures may be obtained. As long as the same metal is used each time, the temperature is reproducible. The pyrolysis filament, to which the sample is applied, is usually configured as a wire or thin foil so that it may heat rapidly, and elevated temperatures may be achieved in less than 1 s.

Advantages of the Curie-point approach include the ability to apply the sample to a cool surface then heat it rapidly, the ''self-limiting'' nature of the temperature control, that is, the temperature is not set by the instrument but rather is a function of the metal used, the ability to use a fresh wire for each sample and the availability of autosamplers.[34] Disadvantages include being limited in temperature selection to the alloys available and having no control over the rate of heating.

3.3 Resistive Heating: Filaments

Resistively heated filament pyrolyzers are similar to Curie-point instruments in that the sample is applied to a metal filament cool, then rapidly heated. The filament is made of a resistive material, generally platinum, which may be heated to any temperature up to about 1400 °C. Temperature control is independent of the filament metal, that is, unlike Curie-point instruments, the filament may be used over a wide range of temperatures, not just one. The temperature and heating rate are controllable electronically, so the filament may be heated ballistically as in a Curie-point instrument, but may also be heated more slowly. Since the temperature is not self-limiting as in a Curie-point instrument, it must be monitored, which may be done by optical pyrometry, with a thermocouple or photodiode or by measuring the resistance of the filament.

Advantages of the resistive filament include the ability to use the same filament at a variety of temperatures and control of both the heating rate and temperature. Since the filament may be configured as a coil to accept a small sample tube, sample placement is more convenient for materials such as powders and fibers. As with Curie-point instruments, automated sample introduction is available. Disadvantages of filament pyrolysis include the more complex temperature measurement and effects of

permanent filament mounting. Since the filament must be attached to the electronic controller, replacement of the heating wire or foil is more involved than for a Curie-point instrument.

3.4 Other Heating Techniques

Some specialized heating techniques have also been applied to pyrolysis instrumentation, which depart from the considerations above. One is the programmable furnace, which is not used isothermally as the isothermal microfurnace. Instead, the sample is placed in a cool furnace, then heated gradually to pyrolysis temperatures, with the production or collection of products along the way. Some devices have been made specially for this purpose, but many analysts have obtained similar results by interfacing an instrument for thermogravimetric analysis (TGA) to a mass or infrared spectrometer. A second application involves the use of lasers to heat the sample, which must frequently be applied to or mixed with an adsorbing material to use the laser energy. Lasers are capable of heating a sample very rapidly, but the difficulty in determining the pyrolysis temperature has limited acceptance of the technique.

4 INTERFACING

Analytically, pyrolysis is almost always used as a sample introduction technique, to extend the use of instruments not normally capable of handling polymers. This means that pyrolysis techniques are generally coupled, and the pyrolyzer must be interfaced to the analytical device. By far the most common interfacing is of a pyrolyzer to a gas chromatograph, but direct interfacing to mass spectrometers and FTIR spectrometers is also common.

4.1 Pyrolysis/Gas Chromatography

Regardless of the detector [MS, flame ionization detector (FID), thermal conductivity detector (TCD) or other] Py/GC first involves transfer of the compounds made by pyrolysis to the inlet of the GC column. Once on the column, the constituents of the pyrolyzate should be handled in the same way as any other mix of materials. There are several important considerations in interfacing a pyrolyzer to a gas chromatograph in a way to ensure that the latter can perform properly. The sample should be created rapidly, transferred rapidly through as short a transfer as possible, with good thermal integrity between the two devices. Resolution of the early eluting peaks will be affected adversely by slow product formation or transfer, causing band broadening. Since pyrolysis may create some relatively large molecules (by GC standards), cold spots between the pyrolyzer and GC column will result in either broad peaks or even the loss of analytes, which may be significant to the analysis.

The most important consideration in connecting a pyrolyzer to a gas chromatograph is the recognition that it is an entirely different means of sample introduction. GC inlets are designed to accept a sample injected in solution using a syringe which is inserted into the GC pneumatics. With pyrolysis, a sample is created upstream of the column and delivered to the injection port along with the carrier gas, with the constituents already in the vapor phase. This is why the rapid pyrolysis, transfer and heated connections are emphasized – anything which retards the delivery of the pyrolyzate volatiles as they are delivered to the GC inlet will adversely affect the chromatography. Further, it is important to understand the pnuematics of the injection port to be sure that the analytes are being delivered to the column and not vented, diluted or adsorbed. In general, all of the GC carrier flow usually introduced to the injector should be routed through the pyrolyzer, then back to the injector for efficient sweeping of the pyrolysis zone. Relatively high split ratios help transfer the pyrolyzate rapidly and prevent column overload, since the small samples compatible with microbore capillaries are frequently exceeded by analysts. In cases where slow pyrolysis rates are required for the experiment, or very low flow rates are needed for sensitivity, cryogenic focusing of the pyrolyzate on to the column before analysis compensates for the band broadening otherwise encountered.

4.2 Pyrolysis/Mass Spectrometry

Even though pyrolysis of a sample may create a complex mixture of materials, and because sometimes it does not, some analysts prefer to interface the pyrolyzer directly to a mass spectrometer,[35,36] eliminating the chromatography. The attraction comes from two considerations. First, the analysis may be done much more quickly if it does not require 30–60 min for the chromatography.[37] Second, the pyrolysis reaction is in immediate contact with the mass spectrometer, so species may be observed which are not delivered through a GC column. Further, the pyrolyzer may be heated in a programmed way and the mass spectrometer used to produce a time- or temperature-resolved analysis[38] by scanning continuously during the heating. To help simplify the data, some analysts perform chemical ionization[39] rather than electron impact ionization, but techniques employing field ionization[40] and potassium attachment[41] have also been employed. In addition to the benefits of a short analysis time and time-resolved studies, the spectra obtained may be manipulated by the software of the mass spectrometer for comparison and recognition. Although some success has been demonstrated by interfacing a pyrolyzer

designed for GC applications to the mass spectrometer using a short, inert transfer line, most applications have used specially designed solids probes capable of heating to high temperatures or other direct modifications to the mass spectrometer inlet.

4.3 Pyrolysis/Fourier Transform Infrared Spectroscopy

For many of the same reasons that analysts have interfaced pyrolyzers to mass spectrometers, systems for pyrolysis/Fourier transform infrared (Py/FTIR) spectroscopy have also been devised. These systems may involve a flow of carrier gas from the pyrolyzer into a light pipe in the FTIR instrument,[42] or the design of a specific cell to fit in the FTIR instrument which contains a pyrolysis filament.[43] The ability of the FTIR instrument to scan continuously over a temperature regime permits, as with pyrolysis/mass spectrometry (Py/MS), the display of spectra associated with a particular temperature to help elucidate the degradation pathway of a polymer.[44]

4.4 General Considerations

Regardless of the type of interfacing between the pyrolyzer and the analytical device, the sample to be pyrolyzed and the pyrolyzate it makes must be compatible with the analyzer. Many analytical instruments are designed for sensitivity and are capable of handling only very small samples. The total sample delivered from the pyrolyzer should not exceed that sample capacity. In the case of synthetic polymers, the sample is extensively degraded, so the mass of the original sample should be no more than is usually introduced into the system when not using a pyrolyzer. In GC, for example, a 1-μL injection of a solvent is substantial, representing approximately 1 mg. Polymer samples for introduction should therefore be of the same general amount, and 10–100 μg is considered optimal by many analysts. Consideration must be paid to the materials generated during pyrolysis, since they will be transferred to the analytical device directly. Polymers which produce very large oligomers may eventually contaminate the inlet, requiring more frequent cleaning or the installation of a guard to remove contaminants before they enter the system. Likewise, some polymers generate corrosive or reactive species, and the effect of those on the analytical system must be considered. PVC, for example, generates HCl, which does not preclude its analysis by GC/MS, but does advocate the use of small samples and adequate purging. Finally, since small solid samples are being used, the opportunity to contaminate them and introduce extraneous analytes is always present. When introducing 50 μg of a plastic material, the chance that it contains finger oils, adsorbed volatiles or residues from other samples must always be considered.

5 APPLICATIONS

5.1 Polyolefins

Polyolefins almost always degrade by chain-bond scission to form monomer and higher oligomers, frequently producing considerable amounts of trimer via the 1–5 hydrogen transfer mechanism. Examples of polyethylene and polypropylene are shown in Figures 1 and 3, respectively. Polyolefins made from larger monomers show the same tendency, i.e. a repeating pattern of oligomeric peaks, with the oligomeric materials becoming increasingly larger molecules. Poly(1-butene) therefore produces the pattern seen in Figure 8, in which the largest peak at 9 min is the trimer of 1-butene.

5.2 Polyamides

The synthetic polyamides nylons have been extensively studied via pyrolysis.[28] Nylons may be formed in two ways, either using a single monomer with an acid group at one end and an amine at the other, or by using two monomers, a dicarboxylic acid and a diamine. The single-monomer nylons are given a single number, such as nylon 6, indicating that the monomer has six carbons, and the two-monomer type are given two numbers, such as nylon 6,12, indicating the number of carbons in the diamine and diacid, respectively.

When pyrolyzed, nylons generate a variety of compounds, including nitriles, dinitriles, lactams and hydrocarbons. Nylon 6, for example, produces extensive amounts of caprolactam, producing a pyrogram such as that shown in Figure 9. Nylon 6,6, although structurally similar, produces nitriles and a large peak of cyclopentanone from the C_6 diacid portion of the molecule. This cyclopentanone is a common pyrolysis fragment in nylons synthesized with the six carbon diacid, regardless of the length of the diamine. Figure 10 shows a pyrogram of nylon 6,6 for comparison with nylon 6 in Figure 9.

5.3 Polyesters

The most common polyesters are phthalic acid polymers made with polyfunctional alcohols. Many paints are glycerol phthalate polyesters, including house-paints and the automotive finishes used before PMMA and styrene copolymers were introduced. Poly(ethylene terephthalate) (PET) is the most commonly encountered polyester, comprising the bulk of polyester textile fibers, beverage and food containers and other rugged, inexpensive goods. When phthalate polyesters are pyrolyzed, the most noticeable products are derived from the phthalic acid, and include benzoic acid and other substituted aromatics. Figure 11 shows the pyrogram produced from a piece of overhead projector transparency film, which is PET,

Figure 8 Pyrogram of poly(1-butene).

with the two peaks eluting at about 11 min being vinyl benzoate and benzoic acid.

5.4 Polyurethanes

Polyurethanes are produced using a di- or triisocyanate and a multifunctional alcohol. The OH providing monomer is frequently a ester or ether with two or more OH groups attached, while any of several diisocyanates is commonyl used, including toluene diisocyanate (TDI) and hexane diisocyanate. Polyurethanes are used in protective coatings and synthetic rubber, as in the foam ''rubber'' used in many furniture applications. An interesting property of polyurethanes when pyrolyzed is that they generally regenerate the original diisocyanate used in the polymerization, making the identification of a polyurethane relatively easy. The chromatograms produced from pyrolyzing polyurethanes are usually fairly simple, as in the example in Figure 12. This is a piece of polyurethane foam used for padding, and the large peak at 19 min is TDI.

5.5 Vinyl Polymers

PVC, PVDC and PVA pyrolyze to release HCl and acetic acid respectively, as discussed in section 2.2. For many applications, such as binder covers and plastic tubing, PVC is extensively plasticized, usually with a phthalate plasticizer. The clear, pliable, plastic tubing used in many laboratory applications is generally heavily plasticized PVC, and when a piece of such tubing (or similar material) is analyzed via pyrolysis, the plasticizer is usually seen in the chromatogram along with the pyrolysis products of the PVC. Since the plasticizer is probably volatile at the operating temperature of the pyrolyzer, it is usually desorbed intact before pyrolysis takes place, and the resulting chromatogram looks like Figure 13. The early eluting peaks here include HCl (at 2 min), benzene, toluene and naphthalene, all indications of PVC, while the large peak at 26 min is bis(2-ethylhexyl) phthalate.

5.6 Acrylics

Since the polyacrylates can undergo a 1–5 hydrogen transfer and form trimers, and the polymethacrylates

Figure 11 Pyrogram of a piece of PET transparency film.

cannot (section 2.1), the overall pyrograms of these related polymers are easily distinguished. A pyrogram of PMMA is shown in Figure 2, with MMA monomer making the large peak at 3 min. Materials made essentially of PMMA, including Plexiglas™ and countertops such as Corian™, will produce a pyrogram which closely resembles Figure 2. Similarly, poly(ethyl methacrylate) will produce mostly ethyl methacrylate monomer, and so on. Poly(butyl methacrylate) will produce a large peak for monomer, but poly(butyl acrylate) will generate monomer, dimer and trimer. Figure 14 is a pyrogram of poly(butyl acrylate), showing the monomer at 5 min and a large peak for the trimer at 24 min.

5.7 Copolymers

Since most polymeric goods are not simple homopolymers, the utility of pyrolysis is measured by the information it provides on copolymeric systems. Figures 5–7 show both the ability to identify the monomers and the relative amounts of monomers in a ethylene–propylene copolymer, and to distinguish random from block copolymers. The same is true for other copolymers of olefins, and also for the myriad of copolymers using dissimilar monomers. Synthetic rubbers, for example, may be copolymers of styrene, butadiene, acrylonitrile, isoprene, chloroprene and many other monomers. Even in the presence of fillers such as carbon black,[45] however, information is readily generated as to the monomeric composition of these products. Figure 15 is the pyrogram of a piece of automobile tire rubber, extensively filled with carbon black. The rubber portion is a copolymer of butadiene and isoprene, and both monomers and dimers for each can be seen. The two large peaks which elute first (just before 2 min) are butadiene and isoprene, respectively, then the butadiene dimer elutes at 6 min, with the tall peak at 11 min being the isoprene dimer. Many other natural and synthetic rubber formulations have been analyzed,[46] including styrene–butadiene (SBR), styrene–isoprene and acrylonitrile–butadiene–styrene (ABS) copolymers.

Acrylic copolymers, with and without styrene, are used in a wide array of consumer goods from automobile paint to photocopy toner. Since many of the monomers (the methacrylates) produce mostly monomer whereas others (styrene, the acrylates) also produce dimers, trimers and higher oligomers, the product distribution

Figure 13 Pyrolysis of PVC with plasticizer. The peak at 26 min is bis(2-ethylhexyl) phthalate.

Figure 14 Pyrogram of poly(butyl acrylate). The large peak at 24 min is the trimer of butyl acrylate.

Figure 15 Pyrogram of automobile tire rubber (copolymer of butadiene and isoprene).

depends both on the monomers used[47] and on the type of copolymer (random or block).[48,49] Whether or not there are enough monomeric units together in the chain to produce homotrimers, these copolymers efficiently generate monomer peaks for each of the monomers used, providing both qualitative and quantitative information. Automobile finishes use a wide array of monomers, including styrene, MMA, ethyl acrylate, butyl acrylate,

Figure 16 Pyrolysis of automotive paint formulated with MMA, styrene, butyl acrylate, butyl methacrylate and hexyl methacrylate.

Figure 17 Pyrogram of a photocopy toner showing monomers for styrene and butyl acrylate at 5 min and trimers at 25 min.

Figure 18 Pyrolysis of a vinyl chloride–vinylidene chloride copolymer.

butyl methacrylate, hydroxy-substituted methacrylates, longer chain methacrylates for flexibility and a variety cross-linking agents.[50] An example of such an automotive paint is shown in Figure 16. Monomers used in the formulation include MMA, styrene, butyl acrylate and butyl methacrylate, which elute at 3.2, 6.9, 7.0 and 9.1 min respectively. In addition, flexibility is gained by adding the monomer hexyl methacrylate, which elutes at 16.5 min.

Since both polystyrene and poly(butyl acrylate) pyrolyze to give monomer, dimer and trimer, styrene–butyl acrylate copolymers should produce these oligomers, and a random copolymer will produce mixed oligomers. The relative abundances of the various homo- and co-oligomers depend on the relative amounts of the two monomers in the copolymer. An example of this is seen in Figure 17, which shows an analysis of a photocopy toner, a copolymer which is mostly styrene with some butyl acrylate. The sytrene monomer and butyl acrylate monomer elute next to each other at about 5 min, with the large styrene peak eluting first and the butyl acrylate the small peak immediately after it. At about 25 min there are three peaks which comprise trimers for the system, the largest of which is the styrene homotrimer, since the amount of styrene in the polymer makes it very likely that there will be three styrenes adjacent to one another to form the trimer.

Vinyl copolymers[51] have also been studied. As discussed in section 2.2, PVC degrades to make HCl and aromatics, including benzene, whereas PVDC gives chiefly HCl and trichlorobenzene. The copolymer of vinyl chloride and vinylidene chloride shown in Figure 18 can be seen to contain more vinylidene chloride than vinyl chloride because of the relative amounts of the primary degradation products. There is almost no benzene (2 min), some chlorobenzene (4.8 min), considerable dichlorobenzene (8.8 min), but mostly trichlorobenzene (12 min), the primary product from PVDC.

In general, then, almost any polymeric material may be characterized using a combination of pyrolysis and a routine analytical device. The availability of automated pyrolysis equipment and inexpensive mass spectrometers makes this an attractive combination for the characterization of polymers, whether new formulations or applications of materials which have been in the marketplace for decades.

ABBREVIATIONS AND ACRONYMS

ABS	Acrylonitrile–Butadiene–Styrene
FID	Flame Ionization Detector

FTIR	Fourier Transform Infrared
GC	Gas Chromatography
GC/MS	Gas Chromatography/Mass Spectrometry
MMA	Methyl Methacrylate
MS	Mass Spectrometry
PET	Poly(ethylene terephthalate)
PMMA	Poly(methyl methacrylate)
PVA	Poly(vinyl acetate)
PVC	Poly(vinyl chloride)
PVDC	Poly(vinylidene chloride)
Py/FTIR	Pyrolysis/Fourier Transform Infrared
Py/GC	Pyrolysis/Gas Chromatography
Py/MS	Pyrolysis/Mass Spectrometry
SBR	Styrene–Butadiene
TCD	Thermal Conductivity Detector
TDI	Toluene Diisocyanate
TGA	Thermogravimetric Analysis

Size-exclusion chromatography (SEC) is a standard technique for determining molar mass averages and molar mass distributions (MMDs) of polymers. Sometimes the terms gel permeation chromatography (GPC) or gel filtration chromatography (GFC) are also used, but SEC should be preferred, because this term describes the mechanism much better: polymer molecules are separated according to their hydrodynamic volumes (which can be correlated with molar mass), with the larger size molecules exiting first followed by the smaller. Molar masses are determined either from a calibration or using molar mass sensitive detectors. In the case of copolymers, the knowledge of chemical composition along the MMD is required, which can be obtained from combinations of different concentration detectors. As the hydrodynamic volumes of different polymers are typically somewhat different, molecules with different chemical composition and different molar mass will be eluted in the same slice of the chromatogram. Obviously, a discrimination between such molecules requires a two-dimensional separation, in which one dimension may be SEC, and the other one a chromatographic technique, which separates according to chemical composition rather than molar mass, such as liquid adsorption chromatography (LAC), liquid chromatography at the critical point of adsorption (often also called liquid chromatography under critical conditions, LCCC), supercritical fluid chromatography (SFC), temperature rising elution fractionation (TREF), etc.

In the lower molar mass range, mass spectroscopy competes with SEC. The most frequently used technique is matrix-assisted laser desorption/ionization time-of-flight mass spectroscopy (MALDI/TOF/MS), which cannot, however, provide quantitatively accurate MMDs. Due to its excellent resolution in molar mass, it can be combined with chromatographic techniques in order to increase the reliability of the analysis.

1 INTRODUCTION

In the characterization of polymers, SEC has become a standard technique for determining molar mass averages and MMDs of polymers. Depending on the field of application, different terms have been used: in biochemistry and related areas the term GFC is usual, while GPC is commonly used in the analysis of (synthetic) polymers.

The principle of SEC is rather easily understood. Due to limited accessibility of the pore volume within the particles of the column packing, polymer molecules are separated according to their hydrodynamic volumes, with the larger size molecules exiting first followed by the smaller. Residence time can be correlated with molar mass. The correlation obtained then depends upon the type of polymer.

1.1 History

The origins of SEC date back to the early 1960s. In 1959, Porath and Flodin described the separation of water-soluble macromolecules on cross-linked polydextrane gels. As soon as these gels had become commercially avaliable, they were extensively used for separating biomolecules by the new technique, which was called GFC, typically in low pressure systems.[1]

In 1964, J.C. Moore of the Dow Chemical Company disclosed the separation of synthetic polymers on cross-linked polystyrene (PS) gels in organic mobile phases. The new technique was called GPC and very soon became a standard method for the determination of MMDs.

2 APPLICATIONS

Basically, SEC separates according to the size of a species in solution (the hydrodynamic volume). This species may be a single molecule, a polymer coil, an aggregate, a micelle, etc. Hence, SEC can be applied to determine the molar mass of a polymer and also to study aggregation phenomena in solution.

Typically, SEC is applied to the analysis of synthetic polymers and oligomers,[2–7] coal-derived substances,[8–10] lipids,[11,12] and natural macromolecules (such as proteins,[13–15] poly(ethylene glycol) (PEG)-modified proteins,[16,17] glucans,[18,19] cellulose derivatives,[20,21] humic substances,[22] crude-oil alkanes[23]).

SEC may also be used in studying processes accomplished by a change of the hydrodynamic volume of polymers or small molecules (such as lipids[12,24–26]): degradation,[27,28] hydrolysis,[21,29] refolding of proteins,[30] polymerization,[31–35] aggregation,[36,37] etc.

3 RELIABILITY OF SIZE-EXCLUSION CHROMATOGRAPHY

In the last few years several round-robin tests have been performed with different kinds of polymers[38–45] in order to evaluate the reproducibility of SEC and the precision and accuracy of the results thus obtained.

There may be various sources of error responsible for the differences in the results obtained at different laboratories, as can be easily understood from Figure 1, in which the experimental set-up and the basic steps in obtaining an MMD for a polymer sample are shown schematically. An appropriate mobile phase is delivered to a chromatographic column filled with a suitable stationary phase by a pump at a constant and reproducible

Figure 1 Schematic representation of SEC.

flow rate. Into this solvent stream a small amount (typically 0.01 to 1.0 mg) of the polymer sample is injected.

The separated fractions are detected by at least one detector, the signal of which must represent the concentration of the polymer with good accuracy. From the concentration curve thus obtained the MMD is calculated.

Provided that the separation itself is reliable (which cannot always be taken for granted!), the subsequent transformations are subject to errors:

1. Elution time to elution volume. This requires a highly constant and reproducible flow rate, which means that only high quality pumps should be used.
2. Elution volume to molar mass. The molar mass of a fraction can be obtained either from a calibration or from a molar mass sensitive detector (in addition to the concentration detector).
3. Detector response to polymer concentration. This requires a sufficiently wide linear range, a well defined response of the detector(s) along the entire peak (i.e. for all molar masses within the MMD), and – in the case of copolymers – a second concentration detector.

In the following sections, each step will be referred to in detail. Requirements concerning sample treatment, chromatographic equipment, data acquisition and processing will be discussed and different approaches to the analysis of different types of polymers evaluated.

4 COMPONENTS OF A SIZE-EXCLUSION CHROMATOGRAPHY SYSTEM

As there are considerable differences between SEC and other types of high-performance liquid chromatography (HPLC), the criteria for achieving high performance are somewhat different. In this section, the main components of an SEC system and their influence on the quality of the analysis shall be discussed.

4.1 The Mobile Phase

The mobile phase in SEC must be a good solvent for the polymer in order to avoid nonexclusion effects,[46,47] which will be discussed later on. It is also important to dissolve the sample at appropriate temperature and sufficiently long before injecting it in order to allow the coils to swell in the solvent or to break down aggregates.[48] In some cases, the addition of electrolytes can be required to achieve disaggregation.[49] As some polymers – such as polyolefins – are typically analyzed at high temperatures (140–150 °C) in rather toxic mobile phases (trichlorobenzene, etc.), alternative solvents would be desirable.[50]

An important question concerns preferential solvation: When a polymer is dissolved in a mixed solvent, the composition of the latter within the coils can be different from outside because of different interactions of the polymer with the components of the solvent. When the sample is separated on the column from the zone, where the solvent would elute, a system peak (vacancy peak) appears, which is due to the missing component of the mobile phase. Obviously, the missing amount of solvent in the system peak appears in the peak of the polymer, the area of which is now different from what it would be in absence of preferential solvation. Even though this effect has been known for a long time, it is often neglected by chromatographers, because they consider their mobile phase to be a ''pure'' solvent, which is, however, generally not the case: even HPLC-grade solvents are seldom more than 99.9% pure, and even then the concentration of the sample is in the same order of magnitude as the impurity. Moreover, solvents may take up moisture from the air, form peroxides, etc. (for example, chloroform typically contains 1% of ethanol or 2-methyl-butene as a stabilizer).

Hence it is important to dissolve the sample in the solvent from the reservoir and not from another bottle. If a solvent peak is observed, this is a strong hint for preferential solvation. Preferential solvation is often neglected, which is acceptable if its contribution does not vary along the MMD. If, however, the end groups of the polymer are considerably different from the repeating units, preferential solvation depends on molar mass, as has been shown recently.[51] A similar effect can be expected in copolymers, if their composition varies with molar mass.

4.2 The Pump

As has already been mentioned, a highly constant flow rate has to be maintained during the entire chromatogram. This is very important in SEC: due to the logarithmic relation between molar mass and elution volume a change of the flow rate of only 0.1% can cause an error in molar mass of up to 10%![52] This requires a pump of very good quality or a compensation of flow rate variations. Unfortunately, most pumps can only reproduce the flow rate to 0.2–0.3%, and this precision can be reduced by leakages in the system or increasing back pressure from the column. Moreover, the check valves as well as the pump seals may limit flow rate precision. In-line filters in the solvent reservoir may prevent particles from coming into the pump heads, which might damage the check valves or the pump seals. One should, however, take into account, that even stainless steel filters may corrode in some solvents. It is trivial that rust particles will have the same effect.

There have been attempts to determine the flow rate by measuring the travelling time of a thermal pulse along a capillary, but generally the precision of these devices is not sufficient. The more efficient – and cheaper – approach is the use of a low molecular internal standard in the MMD calibration and in each chromatogram. The corrected flow rate is obtained from the ratio of the elution times of this standard peak.

The absolute flow rate (in the calibration) can also be obtained by measuring the time to fill a calibrated flask or by weighing the solvent passing the system in a defined time.

It must, however, be said, that the knowledge of the absolute flow rate is not absolutely necessary, as long as flow rate variations are compensated by using an internal standard. It is important that such a correction works well only if the flow rate is sufficiently constant within the entire chromatogram!

4.2.1 Types of Pumps

Basically, one has to distinguish between the following types of pumps, the performance of which may differ

considerably (as well as their suitability for high-performance SEC):

- Syringe pumps. This type of pump works like a large syringe, the plunger of which is actuated by a screw-feed drive (usually by a stepper motor). Therefore it delivers a completely pulseless flow, which is especially important for systems using a viscosity detector.
- Reciprocating pumps. This group comprises almost all commercially available pumps: single piston pumps are cheap, but not well suited for SEC; dual piston pumps can have the pistons arranged parallel or in series. The former pumps deliver a smoother flow, the latter are easier to maintain, because they have only two check valves instead of four. The problem of pulsations can be solved by using a pulse dampener.

4.3 The Column(s)

Unlike in other modes of HPLC, the separation efficiency comes only from the stationary phase, while the mobile phase should have no effect. The whole separation occurs within the volume of the pores, which typically equals approximately 40% of the total column volume. This means that long columns or often sets of several columns are required. Therefore, the right choice of the column(s) for a given polymer is the crucial point.

4.3.1 Commercially Available Columns

Basically, there are different types of SEC columns on the market. The typical column diameters are 7.5–8 mm for analytical columns and 22–25 mm for (semi)preparative columns; usual column lengths are 25, 30, 50, and 60 cm. Recently, narrow bore columns with a diameter of 2–3 mm have been introduced, which save time and solvent.

The packings are based on either porous silica or semirigid (highly crosslinked) organic gels, in most cases copolymers of styrene and divinylbenzene. There are, however, other polymer-based packings available, which can be used in different mobile phases.

In general, silica-based packings are rather rugged, while organic packings have to be handled very carefully, as will be pointed out later on.

4.3.2 Selecting Size-exclusion Chromatography Columns

When selecting columns for a given separation problem in SEC, one may choose from a large number of columns from different producers. Many producers offer columns of the same type, which are comparable and sometimes almost equivalent. In general, the following considerations may lead to the choice of an appropriate column or column set:[53]

- The separation range should be selected carefully, as it does not make sense to use a column with an exclusion limit of 10^6 when analyzing low molecular products. On the other hand, the high molecular end of the MMD should still be below the exclusion limit.
- The particle size, which determines the plate height, has also to be taken into account. Small particles (typically 5 μm) provide a better resolution (higher plate numbers) and achieve the same separation with a smaller overall column length than larger ones (10 μm), but produce a higher back pressure for a given column length. Shorter columns save time and solvent. On the other hand, 5 μm (or even 3 μm) packings are more sensitive towards contamination by samples containing impurities.
- Small particle size packings can sometimes result in shear degradation of large polymer molecules because the space between particles is very narrow. Particles as large as 20 μm have been recommended for very high-molecular-weight polymers. However, axial dispersion (band spreading) effects are then increased.
- Combinations of packings with a different separation range can be achieved by using either columns with different porosity or mixed-bed columns, which typically provide a better linear calibration than combinations of columns.
- When combining columns to a set, one should prefer two 60 cm columns to four 30 cm columns, because the column ends as well as the connections increase peak broadening.
- The chemical nature of a column packing can be crucial: some packings must not be used in certain mobile phases or at higher temperatures, which are required in SEC of polyolefins. Moreover, non-exclusion effects can also be due to an inadequate stationary phase. There may be considerable differences between packings with similar specification, which are mostly due to the residual emulsifiers used in their production.

4.3.3 Handling Size-exclusion Chromatography Columns

Unlike with other HPLC columns, several precautions have to be taken in the use of SEC columns.

- A column set in SEC should be always run in the same mobile phase. This is not only because a different solvent will require a new calibration, but mainly because a solvent change can reduce column life and performance. If, however, a solvent change is

necessary (for example, to remove contamination from the packing), this should be done step-wise (using mixtures of solvents 1 and 2) and at a low flow rate (0.5 ml min^{-1} maximum). For some solvents, a direct change should be avoided by using an intermediate solvent. When switching back to the first mobile phase, the column set should be recalibrated, anyway.

- SEC columns should never be operated in a backward direction, because this may destroy the column packing immediately. Some columns will survive such a procedure, but one should not take that for granted.
- Care should also be taken in connecting columns or in sample injection: one single air bubble injected onto the column can damage the packing!
- Replacing a clogged inlet frit is a dangerous operation, which can also considerably reduce column performance. When analyzing samples, which may contaminate a column, one should always use a pre-column.
- Pulsations from the pump, which can be due to air bubbles in the solvent line, a leakage of one pump seal, or a damaged or dirty check valve, can also reduce column life.

4.3.4 Enhancing Separation Efficiency by Recycling

In SEC, the separation efficiency of a given type of packing depends on the column length, i.e. on the number of columns, which can, however, only be increased to a certain limit, which depends on the resulting back pressure. Reducing the flow rate is not a good solution, because at very low flow rates (far away from the optimum in the van Deemter equation) the plate height increases considerably.

A simple approach towards enhanced separation efficiency is recycling using the alternate pumping method, as shown in Figure 2 for a set of four columns, which are connected to a six-port–two-position valve.[7]

When the peak of interest is still in column 4, the valve is actuated (thus changing the order of the columns to 3-4-1-2), and the peak will leave column 4 to go back to column 1 instead of entering the detector. The overall column length is now 6 instead of four (1-2-3-4-1-2).

Before the peak leaves column 2, the valve is switched again, and the overall column length is again increased by two to yield 8 columns. This procedure can be repeated, as long as the entire peak fits into one half of the column set. Typically, three to four switches are allowed, thus making a column set of 10 to 12 out of 4 with the back pressure of only four columns.

Obviously, a good separation is only one part of a good analysis. Another crucial point is the detection of the fractionated sample leaving the column.

Figure 2 Schematic representation of alternate column recycle SEC.

4.4 Detectors

Among the numerous HPLC detectors, only a limited number can reasonably be applied in SEC. Basically, one has to distinguish the following groups of detectors:

4.4.1 Concentration Sensitive Detectors

It is trivial that at least one concentration sensitive detector has to be used in an SEC system. In the analysis of copolymers, a second concentration sensitive detector is required, the sensitivity of which towards the components of the polymer differs from that of the first detector.

Within the concentration sensitive detectors, one has to distinguish detectors measuring a (bulk) property of the eluate and detectors measuring a property of the solute. Evaporative detectors remove the mobile phase by evaporation prior to detection.

4.4.1.1 Bulk Property Detectors The most familiar instrument in SEC is the refractive index (RI) detector, which exists in various modifications. Its main advantage is that it can be applied in the analysis of almost any polymer.

The density detector, which has been developed in the group of the author, utilizes the principle of the mechanical oscillator and has been described in several publications.[54–56] It can be used in SEC (as an alternative

to the RI detector) and provides valuable information in the analysis of aliphatic polymers, when combined with the RI detector. This instrument is commercially available from CHROMTECH, Graz, Austria. The measuring cell of such an instrument is an oscillating, U-shaped capillary, the period of which depends on its reduced mass, and thus on the density of its content. Period measurement is performed by counting the periods of a time base (an oven-controlled 10 MHz quartz) during a predetermined number of periods of the measuring cell. The signal of such a detector is thus inherently digital, and its response is integrated over each measuring interval.

4.4.1.2 Solute Property Detectors The most familiar solute property detector is the ultraviolet (UV) absorption detector, which exists in different modifications and is available from most producers of HPLC instruments. It can be applied to polymers containing groups with double bonds, such as aromatic rings, carbonyl groups, etc., but not to any other polymers. Typical detection wavelengths are in the range of 180–350 nm, which can, however, be utilized only in solvents with a sufficiently low absorbance. Many typical SEC solvents allow detection only above a wavelength of 250 nm.

Infrared (IR) detectors are limited to certain mobile phases that are sufficiently transparent at the detection wavelength.

4.4.1.3 Evaporative Detectors Evaporative detectors vaporize the mobile phase, and the nonvolatile components of the sample can be detected on-line or off-line.

In the evaporative light scattering detector (ELSD),[12,23,26,57–59] the eluate is nebulized in a stream of pressurized gas and the solvent is evaporated from the droplets. Each droplet containing nonvolatile material forms a particle, which scatters the light of a transversal light beam. The intensity of the scattered light should reflect the concentration of nonvolatile substances in the eluate. There are, however, serious problems in quantification of the signal.[60–63]

It is also possible to use other types of evaporation devices as an interface to a flame ionization detector (FID),[64] a mass spectrometer or a Fourier transform infrared (FTIR) spectrometer.[65–68]

4.4.2 Molar Mass Sensitive Detectors

Molar mass sensitive detectors are very useful in SEC, because they yield the molar mass of each fraction of a polymer peak. As the response of such a detector depends on the concentration as well as the molar mass of the fraction, it has to be combined with a concentration sensitive detector.

Basically, the following types of molar mass sensitive detectors are on the market:

- low angle light scattering (LALS) detectors;[47,69–78]
- multiangle light scattering (MALS) detectors [see references1 21,70,75,77,79–85];
- differential viscometers.[86–90]

The information which can be obtained from such a detector is somewhat different. From light scattering detection, the absolute MMD can be determined directly. With LALS (measuring the scattering intensity at just one angle), no information is obtained on polymer conformation. Using more than one angle, one may also obtain the radius of gyration.

On the other hand, SEC with viscosity detection yields the intrinsic viscosity distribution (IVD). The MMD is, however, determined indirectly (through the universal calibration), and is thus subject to retention errors.

Consequently, it makes sense to combine a light scattering detector with a viscometer detector.[47,69,71–74,76–79] With such a combination, information on branching can be obtained.[89,91–94]

4.4.2.1 Light Scattering Detectors The scattered light of a laser beam passing the measuring cell is measured at angles different from zero. The (excess) intensity $R(\theta)$ of the scattered light at the angle θ is correlated to the weight average of molar mass M_w of the dissolved macromolecules as shown in Equation (1):

$$\frac{K^*c}{R(\theta)} = \frac{1}{M_w P(\theta)} + 2A_2c \tag{1}$$

where c is the concentration of the polymer, A_2 is the second virial coefficient, and $P(\theta)$ describes the scattered light's angular dependence.

K^*, defined in Equation (2), is an optical constant containing Avogadro's number N_A, the wavelength λ_0, RI n_0 of the solvent, and the RI increment dn/dc:

$$K^* = \frac{4\pi^2 n_0^2 (dn/dc)^2}{\lambda_0^4 N_A} \tag{2}$$

Obviously, there will be problems in copolymer analysis if their composition (and thus the RI increment dn/dc) varies within the MMD. In this case, a second concentration detector will be required, which allows a determination of copolymer composition.

A measurement at more than one angle can provide additional information. In a plot of $K^*c/R(\theta)$ versus $\sin^2(\theta/2)$, M_w can be obtained from the intercept and the radius of gyration from the slope.[70,77,79,81,95]

4.4.2.2 Viscosity Detectors[2,47,69,76,77,86–90,92,93,95–111]
A viscosity detector should yield the intrinsic viscosity $[\eta]$, the so-called limiting viscosity number, given by

Equation (3), which is defined as the limiting value of the ratio of specific viscosity ($\eta_{sp} = (\eta - \eta_0)/\eta_0$) and concentration c for $c \to 0$:

$$[\eta] = \lim_{c \to 0} \frac{\eta - \eta_0}{\eta_0 c} = \lim_{c \to 0} \frac{\eta_{sp}}{c} \tag{3}$$

As the concentrations in SEC are typically very low, $[\eta]$ can be approximated by η_{sp}/c. In viscosity detection, one has to determine both the viscosity η of the sample solution as well as the viscosity η_0 of the pure mobile phase, which can be achieved in different ways.

Viscosity measurement in SEC can be performed by measuring the pressure drop across a capillary, which is proportional to the viscosity of the streaming liquid.

Single capillary viscometers (SCVs) using just one capillary and one differential pressure transducer will be strongly affected by the pulsations of a reciprocating pump. Instruments of this type could be used with a syringe pump to eliminate this problem. (This approach is superior to that using additional pulse dampeners.)

A better, but still not perfect approach is the use of two capillaries (C1 and C2) in series, each of which is connected to a differential pressure transducer (DP1 and DP2), and a sufficiently large holdup reservoir (H) in between. The sample viscosity η is thus obtained from the pressure drop across the first capillary, and the solvent viscosity η_0 from the pressure drop across the second capillary. Pulsations are eliminated in this set-up, because they appear in both transducers simultaneously.

A very sophisticated approach is used in another type of differential viscometer, which is commercially available from Viscotek. In this instrument, four capillaries are arranged similar to a Wheatstone bridge.

In Figure 3, both designs are shown schematically. In the Viscotek instrument, a holdup reservoir in front of the reference capillary (C4) ensures that only pure mobile phase flows through the reference capillary, when the peak passes the sample capillary (C3). This design offers several advantages, the most important of which is a higher sensitivity: the detector actually measures the pressure difference ΔP at the differential pressure transducer (DP) between the inlets of the sample capillary and the reference capillary, which have a common outlet, and the overall pressure P at the inlet of the bridge. The specific viscosity $\eta_{sp} = \Delta\eta/\eta$ is thus obtained from $\Delta P/P$.

The main problem in this concept is that the flow in the system must be divided 1 : 1 between both arms of the bridge. This shall be achieved by capillaries 1 and 2, which must have a sufficiently high back pressure. Nevertheless, when a peak passes the sample capillary, a slight deviation of the 1 : 1 ratio will be observed.

Figure 3 Schematic representation of viscosity detectors: (a) SCV; (b) dual capillary viscometer; (c) Viscotek.

The question of flow rate variations exists, however, also in single or dual capillary viscometers. When the polymer peak passes the measuring capillary, the increasing back pressure leads to a constriction in the system, and thus to a shift of the peak by a weak flow rate fluctuation (Lesec effect).[89,112]

4.5 Data Acquisition and Processing

Software for data acquisition and processing are available from all producers of HPLC equipment. As the requirements of SEC are different from those of other HPLC techniques, standard HPLC software does not fulfill the demands of SEC.

Depending on the nature of samples to be analyzed (whether high or low molecular, homo- or copolymers, etc.) and the equipment used (single or multiple detection), the software should provide special features, which will be discussed in the following sections.

In order to allow calculations not provided by the software, export of data to a spreadsheet or other programs should be possible.

5 THE SEPARATION

In SEC, the separation should be solely governed by size exclusion, which need not always be the case. Aside from an inadequate calibration, nonexclusion effects can cause severe errors. Moreover, low efficiency of the columns or the entire system will cause peak broadening, which also leads to inaccurate results.

5.1 Ideal Size Exclusion

Let us first consider the ideal case, in which size exclusion is governing the separation. As has already been mentioned, the separation in SEC has to be achieved within a volume much smaller than the volume of the column.

It is trivial that no fraction of the sample can be eluted before the interstitial volume V_i (i.e. the volume of the solvent outside the particles of the column packing) has passed the column. This elution volume corresponds to the exclusion limit of the column.

Small molecules, which have access to the entire pore volume V_p, will appear at an elution volume equal to the sum of the interstitial volume V_i and the pore volume V_p.

Molecules of a size between these extremes have access to only a part of the pore volume, hence they will be eluted at an elution volume V_e as shown in Equation (4):

$$V_e = V_i + K_{SEC} V_p \tag{4}$$

where K_{SEC} is the equilibrium constant of a sample in SEC.

The relation between K and the molar mass of a polymer is determined by a calibration, as will be discussed later on.

5.2 Exclusion versus Nonexclusion Effects

The equilibrium constant of a chromatographic separation can be correlated with thermodynamic parameters. The driving force for a separation at the (absolute) temperature T is the change in Gibbs free energy ΔG, defined in Equation (5), which results from the changes in enthalpy and entropy, ΔH and ΔS, respectively:

$$\Delta G = \Delta H - T\Delta S = -RT \ln K \tag{5}$$

In ideal SEC, which should be governed solely by entropy, ΔH should equal zero, and the equilibrium constant K_{SEC} should be given by Equation (6):

$$K_{SEC} = e^{\Delta S/R} \tag{6}$$

where $0 < K_{SEC} < 1$, with $K_{SEC} = 0$ for molecules larger than the largest pore (exclusion limit), $K_{SEC} = 1$ for small molecules, which have access to the entire pore volume V_p.

According to the theory developed by Casassa, the distribution coefficient of a flexible macromolecule with the root-mean-square end-to-end distance R in a slit-like pore with diameter $2d$ will depend on the ratio of sizes of the macromolecule and the pores. Equation (7) shows:

$$K_{SEC} = 1 - \frac{2}{\sqrt{6\pi}} \frac{R}{d} \tag{7}$$

In ideal SEC, elution volumes never exceed the void volume $V_0 = V_i + V_p$.

The opposite is true in LAC, where interactions with the stationary phase occur (whether these interactions are adsorption or partition phenomena is not important). If exclusion phenomena can be neglected (which is the case with nonporous stationary phases or in the case of small molecules and stationary phases with large pores), one may write:

$$V_e = V_i + V_p K_{LAC} \tag{8}$$

The distribution coefficient of LAC is determined by enthalpy:

$$K_{LAC} = e^{-\Delta H/RT} \tag{9}$$

As ΔH (and thus the probability of being adsorbed) increases with the number of groups capable of being adsorbed, K_{LAC} increases exponentially with the degree of polymerization. Consequently, elution volumes typically exceed the void volume considerably (as $K_{LAC} > 1$).

In practice, both exclusion and interaction must be accounted for in LAC. The equilibrium constant K can thus be divided into contributions from ideal size exclusion and adsorption, as shown in Equation (10):

$$V_e = V_i + V_p K_{SEC} K_{LAC} \tag{10}$$

It must be mentioned that even in the absence of adsorption or partition phenomena the separation can be determined by an effect other than (ideal) size exclusion. This effect is called secondary exclusion. It originates from (electrostatic) repulsion of polar groups and has nothing to do with molar mass.[46,47,113]

Mori and Nishimura[49] observed polyelectrolyte effects in SEC of poly(methyl methacrylate) (PMMA) and polyamides in hexafluoro-2-propanol. The addition of sodium trifluoroacetate as an electrolyte suppressed these effects by breaking down hydrogen bonding.

Under special conditions (mobile phase composition, temperature) the enthalpic and entropic terms in Equation (5) may compensate each other, and all polymer chains with the same structure will elute at the same volume (regardless of their number of repeating units),

which means that the polymer chain becomes ''chromatographically invisible''. This situation is utilized in LCCC[96,109,114–130] or liquid chromatography at the critical adsorption point (LCCAP),[131,132] which allows a separation according to other criteria (end groups, branching sites, other blocks in copolymers, etc.).

If a polymer contains different structural units (as is the case in block copolymers or functional oligomers), there may be basically four limiting cases:

1. all components are eluted in ideal exclusion mode;
2. main chain in exclusion mode, (weak) adsorption of end groups;
3. critical adsorption point for main chain, separation of end groups by adsorption;
4. critical adsorption point for main chain, separation of second block by exclusion.

Points 3 and 4 are beyond the scope of this chapter, hence they shall not be discussed in detail. An overview is given in a recent book.[133]

Situation 1 would be the most favorable one, which is, however, rare. In many cases, the calibration functions for different polymer homologous series (with the same repeating unit, but different end groups) can be considerably different. In a systematic investigation, Craven et al.[134,135] have studied the elution behavior of polyoxyethylenes with different end groups (diols, mono- and dimethyl ethers) on a Plgel column in different mobile phases. Considerably different calibration lines were found for the different homologous series in different mobile phases. These differences were explained by combinations of exclusion with partition adsorption effects. In the group of the author similar investigations were performed, which led to very similar results.

5.3 The Problem of Peak Dispersion

When a monodisperse sample is analyzed by chromatography, it will appear as a peak more or less of Gaussian shape and not as a rectangular concentration profile (which it was immediately after injection).

The main reasons for the broadening of peaks are diffusion phenomena in the column, the capillaries, and the detector, which can be minimized, but not completely avoided. Additional broadening can be due to high sample loads, interaction of the sample with the column packing, and an imperfect chromatographic system. Void volumes between the connecting capillaries will lead to a dramatically decreased performance of the system.

It is clear that peak broadening will adversely influence the accuracy of results from SEC, where the peak shape is much more important than the area (which is the interesting parameter in most other HPLC applications).

Basically, a chromatographic peak can be described by the function $F(v)$, the detector response at a given elution volume. It must be mentioned that the actual concentration is not always easily obtained from $F(v)$, as will be discussed later.

This function, shown in Equation (11), results from a convolution of two other functions, $G(v, y)$, which is the shape function of a solute eluting at the mean elution volume y, and $W(y)$, the chromatogram corrected for band spreading:

$$F(v) = \int_0^\infty W(y) G_N(v, y)\, dy \tag{11}$$

This equation is well known in SEC as the Tung axial dispersion equation. It is clear that the deconvolution – the calculation of $W(y)$ from $F(y)$ and $G_N(v, y)$ – can be problematic, because $G_N(v, y)$ is not easily obtained. Sometimes the so-called convolution integral, given in Equation (12), is used instead of the Tung equation:

$$F(v) = \int_0^\infty W(y) G_N(v - y)\, dy \tag{12}$$

Equation (12) is a limiting case of Equation (11), because it explicitly assumes the same normalized shape function for all solutes present and the same spreading (i.e. the same standard deviation in a Gaussian peak). This assumption may not be valid in the SEC of polymers, particularly if very high molecular weight polymers are being analyzed. Different approaches for correcting chromatograms for peak dispersion have been published, which work more or less well.[38,101,111,136–138] Because of the uncertainties in mathematically correcting for axial dispersion, the preferred approach is to utilize a good separation system, which produces low or negligible peak spreading. With today's high resolution columns other sources of error, such as flow variations, an improper baseline, neglect of the molar mass dependence of response factors, etc., are of much more concern.

Mathematical correction of peak spreading makes sense only when molecular weight averages calculated from the chromatograms of standards similar to those of the unknowns to be analyzed do not agree with those known for the standard and provided that other, more likely, sources of error have been minimized.

6 DETERMINATION OF MOLAR MASS

As has already been mentioned, three transformations have to be performed with the chromatographic raw data.

- The first one – time to volume – can be performed very easily using an internal standard, as has already been pointed out.
- The second one – volume to molar mass – requires either a calibration or the use of a molar mass sensitive detector.
- The third one – detector response to concentration (or mass) – will be discussed later. This step is especially important in SEC of copolymers, polymer blends, and oligomers.

6.1 Size-exclusion Chromatography Calibration

As has already been mentioned, the elution volume of a polymer molecule in SEC must be larger than the interstitial volume (exclusion limit) and smaller than the void volume (total permeation). Between these limits, the elution volume increases with decreasing molar mass. Unless a molar mass sensitive detector is used, one has to determine the molar mass of a fraction eluting at the volume V_e from a calibration, which can be obtained in different ways.

6.1.1 Calibration with Narrow Standards

If a series of standards with a narrow MMD is available, their elution volumes have to be determined to establish a calibration, from which the molar mass for a given elution volume is obtained. In classical SEC, a linear relation between $\log M$ and V_e was assumed, which is, however, only a first approximation, the quality of which depends very strongly on the columns used. The calibration function is quite simple in this case, as shown in Equation (13):

$$\log M = A + BV_e \tag{13}$$

where A and B are constants, which can be determined very easily by linear regression. For many columns, the calibration line is, however, sigmoidal rather than linear. In most cases, a polynomial fit can match the experimental points much better, as Equation (14) shows:

$$\log M = A + BV_e + CV_e^2 + DV_e^3 + EV_e^4 + \cdots \tag{14}$$

The coefficients A–E in such a relation have to be determined by regression analysis. This feature is provided by many software packages for SEC. The order of the polynomial fit is, however, critical in some cases: if the number of data points (i.e. the number of standards) is too small, a fit of too high an order may produce an erroneous calibration function. A plot of residuals, i.e. a plot of the percent difference in molecular weight provided by the fitted calibration line compared to the experimental data point at a particular retention volume, plotted versus retention volume is a quick, visual way of evaluating the validity of the fit. The plot reveals whether or not the scatter of data points is random around the fitted line and the magnitude of the difference between the fitted line and the experimental data points.[72]

There can be considerable differences between the calibration lines for different polymers on the same column in the same mobile phase. This is especially important in the analysis of copolymers or polymer blends. Consequently, different molar masses will elute at the same volume when a mixture of two homopolymers is analyzed by SEC. The elution volume of a copolymer should be between the elution volumes of the homopolymers of the same molar mass. If the composition of the copolymer at each point of the peak is known, an approximation will be achieved by interpolation between the calibration lines. The approximation works best for block copolymers.

It must be mentioned that different calibrations for the same polymer will be found on the same column in different mobile phases.

The calibration with narrow standards can be applied to many types of polymers, because appropriate standards have become commercially available for many polymers, and some suppliers provide well characterized standards for speciality polymers.

In the low molecular range, additional data points can be taken from the maxima of oligomer peaks, which are at least partially resolved. If one of these peaks can be identified, this is also possible for the higher oligomers. An extension to even higher molar masses can be achieved by semipreparative separation of oligomers by LAC.[139]

In the analysis of samples for which no narrow MMD standards are available, different approaches have been described in the literature. The most feasible one is the use of molar mass sensitive detectors. Alternatively, mass spectrometric techniques (such as MALDI/TOF/MS) can also be applied in establishing a calibration function.[10,23,140–147]

6.1.2 Calibration with Broad Standards

If a well characterized sample with broad MMD is available, one may use different procedures to establish a calibration fitting these averages. The integral MMD method can be applied if the entire MMD of the standard is known with high accuracy (which is, however, seldom the case). The method may assume that the MMD of the sample can be described by the most probable distribution function, and matches the calibration to this distribution. No assumptions on the shape of the calibration are made; the precision of the method is, however, rather poor at points corresponding to the tails of the distribution.

If only the molar mass averages of the sample are known from independent methods (light scattering or

osmometry), linear calibration methods can be applied. It is clear that with two known parameters only a linear calibration which is defined by two parameters (slope and intercept) can be obtained. However, this method has been expanded to nonlinear calibration curves through the use of more than one different standard. Also, it has been combined with axial dispersion correction theory to provide both a band spreading parameter (i.e. sigma) and a calibration curve.

6.1.3 Universal Calibration

A very elegant approach is based on the fact that in SEC the elution volume V_e of a polymer depends on its hydrodynamic volume, which is proportional to the product of its molar mass M and intrinsic viscosity $[\eta]$.

In a plot of log $(M[\eta])$ versus V_e (on the same column), identical calibration lines should be found for two polymers (1 and 2), which can be considered as universal calibration,[148] as shown in Equation (15):

$$M_1[\eta_1] = M_2[\eta_2] \tag{15}$$

The intrinsic viscosity is a function of molar mass, which is described by the Mark–Houwink relationship, where K and a are constants for a given polymer in a given solvent (at a given temperature), as shown in Equation (16):

$$[\eta] = KM^a \tag{16}$$

Combination of these equations yields Equation (17):

$$K_1 M_1^{a_1+1} = K_2 M_2^{a_2+1} \tag{17}$$

If a column has been calibrated with polymer 1 (e.g. PS), the calibration line for another polymer (2) can be calculated, provided that the constants K and a are known for both polymers with sufficient accuracy, as shown in Equation (18):

$$\ln M_2 = \frac{1}{1+a_2} \ln \frac{K_1}{K_2} + \frac{1+a_1}{1+a_2} \ln M_1 \tag{18}$$

The concept of the universal calibration would provide an appropriate calibration also for polymers for which no narrow standards exist.

For lower molar mass samples the Dondos–Benoit relation,[2,149] shown in Equation (19), is used, which is linear in this region:

$$\frac{1}{[\eta]} = -A_2 + \frac{A_1}{\sqrt{M}} \tag{19}$$

The main problem is the accuracy of K and a, which is rather limited even in the case of polymers for which a sufficient number of well defined standards exists: there are very high variations in the values reported in literature. If one has to rely on these data, there is the question which set of constants would yield an appropriate calibration.

After all, the expense of buying (even costly) narrow standards would be worthwhile in most cases. If such standards are not available, the method of choice will be the use of molar mass sensitive detectors.

7 QUANTIFICATION IN SIZE-EXCLUSION CHROMATOGRAPHY

Once the first two transformations (time to volume and volume to molar mass) have been performed, there remains the third transformation (detector response to amount of polymer in a fraction), which can also be subject to errors, depending on the nature of the samples. In the following section, the particular problems are referred to with respect to the type of polymer to be analyzed.

7.1 Homopolymers and Oligomers

In SEC of polymers, most chromatographers assume a constant response factor within the entire MMD, which is, however, justified only in the analysis of homopolymers with sufficiently high molar mass.

7.1.1 Molar Mass Dependence of Response Factors

The most frequently used detectors in SEC are the UV and the RI detectors. Recently, we have introduced the density detector, which is useful in the analysis of non-UV absorbing polymers.

The UV detector "sees" UV-absorbing groups in the polymer, which may be the repeating unit, the end groups, or both. Basically, there may be two limiting cases:

- If the repeating unit absorbs at the detection wavelength, the signal reflects the weight concentration of the polymer.
- If the end groups can be detected at a wavelength where the repeating units do no absorb, the signal reflects the number concentration of the polymer (provided that the functionality is known). This can be utilized for determining the number of functional groups in oligomers by derivatization with UV-active reagents (as phenyl isocyanate).[150,151]

RI and density detector measure a property of the entire eluate, that means, they are sensitive towards a specific property of the sample (the RI increment or the apparent specific volume, respectively).

It is a well known fact that specific properties are related to molar mass, as shown in Equation (20):

$$x_i = x_\infty + \frac{K}{M_i} \tag{20}$$

where x_i is the property of a polymer with molecular weight M_i, x_∞ is the property of a polymer with infinite (or at least very high) molecular weight, and K is a constant reflecting the influence of the end groups. A similar relation holds for the response factors for RI and density detection, as shown in Equation (21):

$$f_i = f_\infty + \frac{K}{M_i} \tag{21}$$

In a plot of the response factor f_i versus the molecular weight M_i of a polymer homologous series (with the same end groups) one will obtain a straight line with the intercept f_∞ (the response factor of a polymer with very high molecular weight, or the response factor of the repeating unit) and the slope K, which represents the influence of the end groups.[7,152–154]

Different methods can be applied for the determination of f_∞ and K:[155]

- If a sufficient number of monodisperse oligomers is available (as is the case with PEG), linear regression will be the method of choice.
- If at least one sample with very high molecular weight (from which the intercept f_∞ can be obtained) and a polydisperse sample with low molecular weight are available, an iteration procedure can be used to determine K.

Once f_∞ and K are known, the correct response factors for each fraction eluting from an SEC column can be calculated (with the molar mass obtained from the SEC calibration).

Molar mass dependence of response factors – unless compensated – can lead to severe errors, as has been shown in another paper.[7] Ethoxylated fatty alcohols were analyzed using SEC with coupled density and RI detection. While the chromatograms looked quite normal in density detection, the sign of the response for the lower oligomers changed in RI detection: the alkanols and the monoethoxylates appeared as negative peaks, and the diethoxylate was almost invisible.

7.2 Copolymers and Polymer Blends

In the analysis of copolymers, the use of multiple detection is generally inevitable. If the response factors of the detectors for the components of the polymer are sufficiently different, the chemical composition along the MMD can be determined from the detector signals. Typically, a combination of UV and RI detection is used,[156] but other detector combinations have also been described. If the components of the copolymer have different UV spectra, a diode array detector will be the instrument of choice. One has, however, to keep in mind that nonlinear detector response may also occur with UV detection, as Mori and Suzuki[157] have shown. They analyzed PS and copolymers of styrene with methyl methacrylate by SEC with RI and UV detection (at 254 nm) on PS gels in chloroform as mobile phase, and found that the ratio of UV and RI signals increased at the extreme parts of the MMD. Peak dispersion between the detectors, which might have caused a similar effect, was obviously not, or not alone, responsible for the deviations. In a concentration series of PSs, a nonlinear relation between sample size and peak area was found. Lukyanchikov et al.[158] described similar deviations in the analysis of butadiene–styrene copolymers and PS blends with polybutadiene (PB) and poly(dimethylsiloxane) (PDMS) using SEC with UV and refractometric detectors.

In the case of non-UV absorbing polymers, a combination of RI and density detection yields the desired information on chemical composition.[120,124,154,155,159–161] The ELSD cannot be applied because of its poor linearity and its unclear response to copolymers.

The technique can also be applied to oligomers instead of compensating for the molar mass dependence of detector response: in SEC of fatty alcohol ethoxylates or PEG macromonomers, a combination of density and RI detection can be applied as well and yields consistent results.[7,154,161]

The principle of dual detection is rather simple: when a mass m_i of a copolymer, which contains the weight fractions w_A and w_B $(= 1 - w_A)$ of the monomers A and B, is eluted in the slice i of the peak, it will cause a signal $x_{i,j}$ in the detectors, the magnitude of which depends on the corresponding response factors $f_{j,A}$ and $f_{j,B}$, where j denotes the individual detectors. This is shown in Equation (22):

$$x_{i,j} = m_i(w_A f_{A,j} + w_B f_{B,j}) \tag{22}$$

The weight fractions w_A and w_B of the monomers can be calculated using Equation (23):

$$\frac{1}{w_A} = 1 - \frac{(x_1/x_2)f_{2,A} - f_{1,A}}{(x_1/x_2)f_{2,B} - f_{1,B}} \tag{23}$$

Once the weight fractions of the monomers are known, the correct mass of polymer in the slice can be calculated using Equation (24):

$$m_i = \frac{x_i}{w_A(f_{1,A} - f_{1,B}) + f_{1,B}} \tag{24}$$

and the molecular weight M_C of the copolymer is obtained by interpolation between the calibration lines of the homopolymers, as shown in Equation (25):

$$M_C = M_B + w_A(M_A - M_B) \tag{25}$$

where M_A and M_B are the molecular weights of the homopolymers, which would elute in this slice.

The interpolation between the calibration lines cannot be applied to mixtures of polymers: If the calibration lines of the homopolymers are different, different molecular weights of the homopolymers will elute at the same volume. The universal calibration is not capable of eliminating the errors originating from the simultaneous elution of two polymer fractions with the same hydrodynamic volume but different composition and molecular weight![154]

As the molar masses of different polymers eluting at the same elution volume are given by the corresponding constants K and a in the Mark–Houwink equation, one may calculate the molar masses of the homopolymers in a polymer blend, which will be eluted in the same interval, using Equation (26):

$$\ln M = \frac{AV_e}{1+a} + \frac{B - \ln K}{1+a} \tag{26}$$

Basically, in SEC there will always be local polydispersity[162] in each slice of the polymer peak: in the case of homopolymers because of peak spreading, in the case of copolymers and polymer blends because of overlapping chemical composition distribution (CCD) and MMD.[163]

Nevertheless, a discrimination of copolymers and polymer blends is impossible with one-dimensional chromatography! Moreover, the architecture of a copolymer (random, block, graft) has to be taken into account, as Revillon[164] has shown by SEC with RI, UV, and viscosity detection. Intrinsic viscosity varies largely with molar mass according to the type of polymer, its composition, and the nature of its components.

Obviously it is feasible to use a combination of molar mass sensitive detectors, such as a LALS, MALS and viscosity detector with two concentration detectors,[72,163,165] from which the (average) composition for each fraction can be obtained, and thus the amount of polymer in the fraction.[166] When using multiple detection, one has to be aware of errors arising from inaccurate interdetector volume[74,101,108,137,166,167] and peak spreading between the detectors.[133] Bielsa and Meira[136] have studied the influence on instrumental broadening in copolymer analysis with dual-detection SEC, and demonstrated the effect of different corrections. Concentration errors may also influence the reliability of the results.[168] Mourey and Balke[72] have proposed a "systematic approach" for setting up multidetector systems. The approach is needed because, as Mourey and Balke show, in such systems, multiple sources of error are present and often the same error can originate from two different sources. The approach emphasizes the idea of ensuring that each detector alone is functioning correctly by comparing results calculated using only data from that detector with the values known for a standard before using detectors in combination. It also employs a superposition of calibration curves obtained from narrow standards and from molecular weight sensitive detectors to determine the effective volume of tubing between detectors (the effective "inter-detector volume"). This method works very well for broad molelcular weight distribution polymers but not for those with a narrow molecular weight distribution. The configuration of the detector system (whether series or parallel) was not important for broad molecular weight distribution results. It has recently been found that the inter-detector volume as measured from the difference in peak retention volumes of narrow molecular weight distribution standards from one detector to another varied with molecular weight when the detectors were in the parallel configuration and the differential viscometer (DV) was one of the detectors.[169,170] In the series configuration no such dependence was observed. This could partly account for difficulties in analyzing narrow molecular weight distribution polymers in parallel configuration systems and may be due to flow rate variation in different branches of the parallel configuration during elution of a sample.

8 COMPARISON WITH OTHER TECHNIQUES

As the analysis of polymers is a difficult task, different techniques can be applied, some of which yield similar information, while others are rather complementary to SEC.[133,171]

In oligomer analysis, SEC competes with LAC and MALDI/TOF/MS: all three techniques can be applied to determine the MMD and yield comparable results.[172]

8.1 Other Types of Chromatography

Capillary SFC and capillary high-temperature gas chromatography (HTGC) can be applied for the quantitative characterization of nonionic alcohol ethoxylate surfactants[173–176] and other oligomers.[177,178] SFC is also very useful in the analysis of carbohydrates[179] and glycerides,[180] etc.

LAC can be performed in isocratic or gradient mode. While isocratic separations[139,172,181–184] are typically limited to oligomers with a narrow MMD, gradient LAC allows also a separation of higher molar mass samples.

In some cases, chromatograms with fully resolved peaks can be obtained. PEGs can be separated on normal or reversed-phase packings,[185–188] while the separation of surfactants according to their degree of ethoxylation is only possible on normal phases.[189–193] Under similar conditions, polyesters,[194,195] PS[195–197] and other polymers can also be separated according to their degree of polymerization.

On the other hand, LAC is a technique complementary to SEC, which can be used to separate copolymers or polymer blends according to their chemical composition.[61,171,194,198–202]

Gradient elution does not necessarily mean a gradient of solvent composition: recently, temperature gradients have successfully been applied in a new technique called temperature gradient interaction chromatography (TGIC).[203,204]

LCCC allows a separation according to groups (or blocks) different from the polymer chain, which is chromatographically invisible under these special conditions. This technique is highly important in two-dimensional separations, hence it will be discussed there.

TREF can be employed to separate according to quite different criteria: the fractionation process depends on melting temperature, melting enthalpy, average crystallinity, average crystallizable sequence length, and polymer–solvent interaction parameter.[205] It is very useful in the analysis of polyolefins.[42,206] Additional information is obtained by coupling TREF with NMR spectroscopy.[206]

Field flow fractionation in various modifications can also be applied. It has been shown that the results obtained for block copolymers – poly(styrene-*b*-*p*-methoxystyrene-*b*-styrene), poly(styrene-*b*-*p*-methylstyrene-*b*-styrene) and poly(styrene-*b*-*p*-cyanostyrene) – using thermal field-flow fractionation (ThFFF), SEC and light scattering were in satisfactory agreement. ThFFF can also be used to determine the thermal-diffusion coefficients for polydisperse polymers and microgels.[84]

Capillary electrophoresis (CE)[207] can be applied in the separation of PEGs and ethoxylated surfactants.[208] Samples containing no charged group have to be derivatized prior to CE analysis with phthalic anhydride[209–211] or 1,2,4-benzenetricarboxylic anhydride[212] to impart charge and detectability on the neutral polymer.

8.2 Mass Spectroscopy

In the analysis of oligomers (such as nonionic surfactants), fast atom bombardment (FAB), time-of-flight secondary ion mass spectrometry, MALDI, electrospray ionization, and field desorption can be applied.[213] The most frequently used mass spectroscopic technique is MALDI/TOF/MS, which has been applied successfully in the analysis of poly((*R*)-3-hydroxybutanoates),[214] coal-derived liquids[8] and many other oligomers and polymers.

The technique has some considerable advantages. It is rapid, requires very small sample amounts, and its resolution and mass-accuracy are marvellous.

On the other hand, there are serious concerns about the quantitation, for the following reasons:

- Sample preparation and desorption/ionization can introduce serious mass biasing that appears to be due to the characteristics of the MALDI process.[215] There are pronounced effects of solvents, particularly solvent mixtures, used to prepare polymer, matrix, and cationization reagent solutions, on MALDI analysis:[216] solvent mixtures containing a polymer nonsolvent can affect the signal reproducibility and cause errors in average weight measurement. Hence it is important to select a solvent system that will allow matrix crystallization to take place prior to polymer precipitation. If these preconditions are fulfilled, MALDI mass spectrometry can provide accurate molecular weight and molecular weight distribution information for narrow polydispersity polymers.[217]
- Serious problems arise in the analysis of polymers with wide polydispersity: the highest mass molecules in the distribution are not observed unless the more abundant lower mass ions are deflected from reaching the detector.[218]

Polydisperse polymers can be analyzed by a combination of MALDI/TOF/MS with SEC, which can be used to obtain fractions with a narrow MMD.[141,143] Microscale SEC can even be coupled on-line to MALDI/TOF/MS with a robotic interface.[142]

Time-lag focusing MALDI mass spectrometry has been employed to analyse PMMA polymers of industrial relevance.[219] This technique also enables the differentiation of end groups.

9 HYPHENATED TECHNIQUES

The analysis of complex polymers and oligomers is complicated by the fact that there may be several distributions in such samples: MMD, CCD, and type of functionality, eventually also architecture (tacticity, branching, blockiness, etc.). Recently, a combination of SEC with 750 MHz NMR has been successfully applied to determine the MMD and the tacticity of PMMA. The molar mass of the polymer in flowing eluate was determined directly (without a conventional calibration procedure) from the relative intensity of NMR signals due to the end-group and repeating units.[146]

Obviously, a full characterization of such samples is very difficult, if it is possible at all. Anyway, it cannot be achieved by simple analytical techniques.

The goal of a full characterization may be approached in several steps, each of which represents a more or less sufficient approximation and will be subject to particular sources of error, as has already been pointed out in the previous sections.

Concerning the particular case of SEC, the following limitations have to be observed:

- One-dimensional separations with one concentration detector may be applied to homopolymers, where calibration standards are available.
- One-dimensional separations with two concentration detectors may be applied to copolymers, where calibration standards are available for both homopolymers.
- One-dimensional separations with one concentration detector and one molar mass detector may be applied to homopolymers of any type. In the case of copolymers, the chemical composition is required for each molar mass. This can be achieved by a second concentration detector.
- One-dimensional separations with two concentration detectors and one molar mass detector may be applied to copolymers with the same architecture. The determination of molar mass and branching requires, however, one more molar mass detector.
- One-dimensional separations with two concentration detectors and two molar mass detectors (viscometer plus LALS or MALS) may be applied to all copolymers. No discrimination between copolymers and polymer blends is possible even in this case.

Basically, multiple detection always yields only the average composition or molar mass of each fraction: the CCD or type of functionality in addition to the MMD can only be obtained by two-dimensional separations (in some cases, even three or more dimensions would be required, which is, however, not yet possible in practice).

The chromatographic and mass spectroscopic techniques described above (SEC, LAC, LCCC, SFC, field-flow fractionation, and MALDI/TOF/MS), which yield different kinds of information, can be combined in different ways:

- When applied independently, they yield different projections of a three-dimensional surface, which describe complex polymers and oligomers: in the case of copolymers with the axes molar mass, chemical composition, and (weight) fraction (as altitude), in the case of functional oligomers with functionality instead of composition.
- Two-dimensional separations, which allow an independent determination of two distributions, can be achieved by combining different modes of chromatography or by coupling a chromatographic separation to a mass spectrometer (preferably MALDI/TOF/MS).[129]

9.1 Multidimensional Chromatography

The distributions of molar mass and functionality can be determined by orthogonal chromatography.[220,221] This technique was also applied to determine MMD and CCD of poly(ethylene oxide-*b*-propylene oxide)s (with LCCC as the first dimension and SEC or SFC as the second one).[116] The application of SEC and nonexclusion liquid chromatography in the characterization of styrene copolymers was described by Mori.[222] Nonexclusion liquid chromatography for polymer separation can be divided into five separation techniques: adsorption, precipitation (solubility), normal and reversed phases, orthogonal, and adsorption at a critical point.[223]

Methyl methacrylate–methacrylic acid copolymers were analyzed by a combination of normal-phase LAC with gradient elution and SEC.[224]

Random copolymers of *N*-vinylpyrrolidone and 2-methyl-5-vinylpyridine were analyzed by SEC–reversed-phase LAC.[105]

A quantitatively accurate mapping of fatty alcohol ethoxylates can be achieved by a combination of LCCC and SEC with coupled density and RI detection in both dimensions.[225] Alternatively, normal-phase LAC may be used as the second dimension.[226]

On-line coupling of SEC, normal-phase liquid chromatography, and gas chromatography was applied in the characterization of complex hydrocarbon mixtures.[227]

Cross-fractionation of a PS sample blended with a PB, and of butadiene– and styrene–methylmethacrylate copolymers by combining SEC with ThFFF has been described.[228]

PS–poly(ethylene oxide) blends and copolymers were analyzed with respect to CCD and MMD using two-dimensional SEC/ThFFF.[229]

A two-dimensional separation of peptides by SEC/reversed-phase liquid chromatography coupled to mass spectrometry has been described recently.[15]

SEC has also been coupled to anion-exchange chromatography in the analysis of polysaccharides and oligosaccharides.[230]

Coupling of full adsorption–desorption and SEC has been applied to the separation and molecular characterization of polymer blends.[231–234]

9.2 Combination of Size-exclusion Chromatography with Mass Spectroscopy

As has already been pointed out, MALDI/TOF/MS can only be applied to polymers with a narrow MMD. Polydisperse polymers can be analyzed with good accuracy by an SEC fractionation (which yields narrow MMD fractions) prior to mass spectroscopy.[141,143] On the other hand, MALDI/TOF/MS is an excellent tool for establishing SEC calibration functions.[145,147,235] In LCCC of oligomers, it yields information on the type of the functionality as well as on the quality of the chromatographic separation.[129,221]

10 SUMMARY

The potential of SEC in polymer characterization is very high, especially when this technique is combined with other modes (LAC, LCCC, SFC) or with mass spectrometric techniques, such as MALDI/TOF/MS.

Multiple detection is in most cases inevitable: combinations of different concentration detectors provide information on copolymer composition, and with molar mass sensitive detectors one may avoid errors with inadequate calibrations.

For complex polymers (with distributions in molar mass, chemical composition, functionality, etc.) one-dimensional techniques can, however, only provide part of the desired information. For these samples, multidimensional separations will be required. In most cases, one of the dimensions will be SEC, while the other(s) could be (gradient) LAC or LCCC.

ABBREVIATIONS AND ACRONYMS

CCD	Chemical Composition Distribution
CE	Capillary Electrophoresis
DV	Differential Viscometer
ELSD	Evaporative Light Scattering Detector
FAB	Fast Atom Bombardment
FID	Flame Ionization Detector
FTIR	Fourier Transform Infrared
GFC	Gel Filtration Chromatography
GPC	Gel Permeation Chromatography
HPLC	High-performance Liquid Chromatography
HTGC	High-temperature Gas Chromatography
IR	Infrared
IVD	Intrinsic Viscosity Distribution
LAC	Liquid Adsorption Chromatography
LALS	Low Angle Light Scattering
LCCAP	Liquid Chromatography at the Critical Adsorption Point
LCCC	Liquid Chromatography Under Critical Conditions
MALDI/TOF/MS	Matrix-assisted Laser Desorption/Ionization Time-of-flight Mass Spectroscopy
MALS	Multiangle Light Scattering
MMD	Molar Mass Distribution
PB	Polybutadiene
PDMS	Poly(dimethylsiloxane)
PEG	Poly(ethylene Glycol)
PMMA	Poly(methyl Methacrylate)
PS	Polystyrene
RI	Refractive Index
SCV	Single Capillary Viscometer
SEC	Size-exclusion Chromatography
SFC	Supercritical Fluid Chromatography
TGIC	Temperature Gradient Interaction Chromatography
ThFFF	Thermal Field-flow Fractionation
TREF	Temperature Rising Elution Fractionation
UV	Ultraviolet

The mobile phase in supercritical fluid chromatography (SFC) is a substance raised above its critical temperature and pressure which exhibits greater solvating properties together with reduced viscosities and higher diffusivities than its liquid state. The eluting power of supercritical mobile phase can be varied widely by controlling pressure, temperature and composition. Thus, SFC offers many advantages over high-performance liquid chromatography (HPLC) in the characterization of polymers and oligomers. SFC of polymeric substances has been operated so far in the three modes of chromatography: adsorption chromatography for the separation of oligomer homologs, size-exclusion chromatography (SEC) for the determination of molecular weight distribution, and adsorption chromatography at critical conditions for the characterization of functionality type distribution. The combination of SFC with supercritical fluid extraction (SFE) is useful for the analysis of polymer additives, such as stabilizers and plasticizers, in an industrial polymer material. SFC is compatible with most conventional HPLC and gas chromatography (GC) detectors, and can also be interfaced with infrared (IR) spectroscopy and mass spectrometry (MS), etc.

1 INTRODUCTION

SFC utilizes fluids or mixtures of fluids above their critical temperature and critical pressure. Supercritical fluids have higher solute diffusivities and lower viscosities than liquids and more solvating power than gases. Thus, SFC can be used to separate high molecular weight samples which are not suitable for GC analysis. The mass transport properties of supercritical fluids compared with those of liquids offer an advantage of greater speed or greater numbers of theoretical plates than could be achieved with HPLC. The solubilization advantage of supercritical fluid is augmented by the ability to readily vary the eluting power of the fluid by controlling density through changes in pressure or temperature.

Of the many fields where SFC has attracted considerable attention, the field of polymer analysis is one of the most important. The interest in SFC of polymers focuses on different aspects:

1. The separation of individual homologs in oligomer samples. In this area, the determination of the molecular weight distribution is of particular interest.
2. Assay of parallel homologous series by separation according to chemical structures, for example, end-groups. Such information may be interesting for the characterization of polymer surfactants, technical silicone oils, macromonomers, prepolymers of thermosetting resins, etc.
3. Fractionation of individual homologs on a preparative scale. Because each homolog is perfectly monodisperse (uniform) and has a definite molecular weight, the series of pure homologs is useful as model compounds for the study of polymer structures and properties, and as reference materials for polymer characterizations.
4. The use of supercritical fluids in different modes of chromatography: the separations of polymers in

Encyclopedia of Analytical Chemistry

adsorption chromatography, SEC, and chromatography at critical conditions of adsorption. The unique properties of supercritical fluids offer new possibilities in this area.

5. The determination of low-molecular weight compounds in polymers, for example, residual monomers and solvents, oligomers, and additives like stabilizers, plasticizers and surface treatment agents. For the determination of these compounds in a polymer matrix, the combination of SFE and SFC is useful.

2 HISTORY

Since its introduction in 1962 by Klesper et al.,[1] SFC has been shown to possess a large potential for the separation of high molecular weight compounds. In 1969, Jentoft and Gouw[2] reported the first application of SFC to polymer separation. They separated polystyrene with an average molecular weight of 578 into the individual homologs from 2-mer to 18-mer by the pressure-programmed SFC using C8-silica as stationary phase and pentane with 5% methanol as the mobile phase (Figure 1). Fractions were also taken and rechromatographed under the same conditions.[2,3] In the same year, nongradient separation of epoxy resin precursors on a packed column SFC was reported by Sie et al.[4] Hartmann and Klesper,[5,6] and Rogers et al.[7,8] continued to develop SFC with packed columns by applying the technique to polystyrene separations.

Figure 1 SFC chromatogram of polystyrene with an average molecular weight of 578.[2] (Reproduced with permission from R.E. Jentoft, T.H. Gouw, *J. Polym. Sci. Polym. Lett.*, Copyright © 1969, John Wiley & Sons Inc.)

Until the early 1980s, only a limited number of papers were published on the polymer separation by SFC. One of those papers described the separation of poly(methylphenylsiloxane) (Silicone DC-170) in an analytical[9] or preparative scale.[10] Another interesting example is the separation of polymers by SFC operated in the size-exclusion mode.[11] The exclusion mechanism was demonstrated for polystyrenes with molecular weight up to 20 400 and poly(vinylpyrolidone)s with molecular weight up to 40 000 using 1,1-difluoromethane as the supercritical mobile phase.

Novel combination of supercritical mobile phase with open tubular fused silica capillary column was introduced in 1981.[12] By means of the capillary SFC with supercritical carbon dioxide, poly(oxyethylene) derivatives (so called ''ethoxylated surfactants'') were separated into the individual homologous series.[13] SFC on packed columns was also developed on a new basis in the early 1980s, taking advantage of the numerous improvements of high-pressure chromatographic instrumentation that were primarily achieved in HPLC.[14,15] The explosive growth of SFC applications at the end of the 1980s was mainly due to the introduction of sophisticated commercial instrumentation for capillary and packed column SFC; reviews of commercial SFC instruments are available.[16–18] One of the current research trends in polymer characterization by SFC is the combination with multiple detectors such as the evaporative light scattering detector (ELSD), MS, and Fourier transform infrared (FTIR) spectroscopy.

Progress in SFC separation of polymers and oligomers prior to 1990 has been extensively reviewed by Schmitz and Klesper.[19] White and Houck[20] reviewed the use of SFC for analysis of a variety of complex oligomeric mixtures. Biannual reviews by Chester et al.[21,22] since 1990 provide general information of new SFC applications including polymer analysis. Ute[23] reviewed fractionation of polymer homologs by preparative SFC. Tables 1 and 2 summarize the reported examples of SFC separation of various polymers.

3 METHODS AND TECHNIQUES

3.1 Supercritical Mobile Phase

In the early studies of polymer separation, *n*-pentane (critical temperature 196.6 °C, critical pressure 33.7 bar) was employed as a main component of supercritical mobile phase. The use of propane, butane, hexane,

Table 1 Examples of polymer separation by packed column SFC

Polymer sample	MW range	Column	Mobile phase	Initial conditions	Detection	Ref.
Polyethylene	C18–C64	40 cm × 0.25 mm (Develosil ODS, 7 μm)	CO_2	100 °C, 150 atm	FID	Hirata et al.[24]
cis-1,4-Polyisoprene	$5 < DP < 35$	25 cm × 10 mm (Develosil 100-5, 5 μm)	CO_2–CH_3CH_2OH	130 °C, 200 kg cm^{-2}	UV (210 nm)	Kawahara et al.[25]
Polystyrene	Ave. 810	25 cm × 4.6 mm (LiChrosorb Si 100, 10 μm)	CO_2–1,4-Dioxane	145 °C, 250 bar	UV (254 nm)	Schmitz et al.[26]
Polystyrene	3600–600 000	25 cm × 4.6 mm (LiChrosorb Si 100, 10 μm)	Pentane–1,4-Dioxane	250 °C, 165 bar	UV (254 nm)	Schmitz and Klesper[27]
Poly(4-vinylbiphenyl)		25 cm × 4.6 mm (LiChrosorb Si 60, 10 μm)	Pentane–1,4-Dioxane	270 °C, 45 bar	UV (270 nm)	Schmitz et al.[28]
Poly(2-vinylnaphthalene)		25 cm × 4.6 mm (LiChrosorb Si 60, 10 μm)	Pentane–1,4-Dioxane	270 °C, 51 bar	UV (270 nm)	Schmitz et al.[28]
Poly(*N*-vinylcarbazole)		25 cm × 4.6 mm (LiChrosorb Si 60, 10 μm)	Pentane–1,4-Dioxane	270 °C, 41 bar	UV (295 nm)	Schmitz et al.[28]
Poly(2-vinylpyridine)		25 cm × 4.5 mm (Crosslinked polystyrene PRP-1, 10 μm)	CO_2–CH_3OH	90 °C, 29 MPa,	UV (230 nm)	Gemmel et al.[29]
Poly(4-vinylpyridine)		25 cm × 4.6 mm (LiChrosorb Si 100, 10 μm)	Pentane–1,4-Dioxane	270 °C, 51 bar	UV (254 nm)	Schmitz et al.[30]
Poly(methylphenylsiloxane) [DC-710]	Ave. 2600	25 cm × 1.7 mm (SFPAK ODS, 5 μm)	CO_2–Hexane	180 °C, 212 kg cm^{-2}	UV	Takeuchi and Saito[31]
Poly(oxyethylene) [PEG 1540]	Ave. 1540	25 cm × 4.6 mm (Ultrasphere Si, 5 μm)	CO_2–H_2O–CH_3OH–$(C_2H_5)_3N$	272 atm	ELSD	Brossard et al.[32]
Poly(oxyethylene) [Triton X-165]	$6 < DP < 20$	10 cm × 2 mm (Nucleosil C18, 3 μm)	CO_2–CH_3OH	170 °C, 130 bar	UV (278 nm)	Giorgetti et al.[33]
Poly(oxyethylene)	$1 < DP < 12$	25 cm × 4.5 mm (Crosslinked polystyrene PRP-1, 10 μm)	CO_2–CH_3CN	135 °C, 25 MPa	UV (195 nm)	Gemmel et al.[29]
Poly(propylene oxide)	$\overline{M}_n$ 3010	7 cm × 1 mm (ODS silica Vydac 330 Å, 10 μm)	CO_2	80 °C, 100 atm, 10 atm min^{-1}	FID	Dean and Poole[34]
Poly(oxymethylene)	*DP* 10.1	25 cm × 7.2 mm (Crest SIL, 5 μm)	CO_2–CH_3OH	130 °C, 200 kg cm^{-2}, −2 °C min^{-1}	UV (235 nm)	Ute et al.[35]

(*continued overleaf*)

Table 1 (*continued*)

Polymer sample	MW range	Column	Mobile phase	Initial conditions	Detection	Ref.
Poly(oxyphenylene)	$4 < DP < 7$	400 cm × 2.6 mm (*n*-octane bonded to 120/150 mesh Porasil C)	Pentane–CH_3OH	214 °C, 570 psi, 3.5 psi min^{-1}	UV (275 nm)	Jentoft and Gouw[3]
PMMA	$1 < DP < 100$	25 cm × 10 mm (Develosil 100-5, 5 μm)	CO_2–CH_3OH	125 °C, 200 kg cm^{-2}, −1 °C min^{-1}	UV (235 nm)	Ute et al.[36]
Poly(methyl crotonate)	$5 < DP < 11$	25 cm × 10 mm (Develosil 100-5, 5 μm)	CO_2–CH_2Cl_2	160 °C, 200 kg cm^{-2}, −1 °C min^{-1}	UV (235 nm)	Ute et al.[37]
Poly(ε-caprolactone)	$\overline{M}_n$ 2960	25 cm × 10 mm (Develosil 100-5, 5 μm)	CO_2–CH_3OH	90 °C, 200 kg cm^{-2}, −1.2 °C min^{-1}	UV (200–230 nm)	Ihara et al.[38]
Poly(ε-caprolactone)	Ave. 530	25 cm × 4.5 mm (Crosslinked polystyrene PRP-1, 10 μm)	CO_2–CH_3CN	135 °C, 25 MPa	UV (190 nm)	Gemmel et al.[29]
Poly(D-lactide)	$20 < DP < 48$	25 cm × 10 mm (Develosil 100-5, 5 μm)	CO_2–CH_3OH	55 °C, 200 kg cm^{-2}	UV (210 nm)	Ute[23]
Poly(*n*-butyl isocyanate)	$\overline{M}_n$ 4000, $20 < DP < 60$	25 cm × 10 mm (Develosil 100-5, 5 μm)	CO_2–CH_3CH_2OH	90 °C, 200 kg cm^{-2}	UV (235 nm)	Ute et al.[39]
Epoxy prepolymers		125 mm × 4 mm (Spherisorb CN, 3 μm)	CO_2–CH_3OH	70 °C, 350 bar	UV (280 nm)	Aton et al.[40]
Novolac and Resol	$\overline{M}_n$ 366	25 cm × 1.7 mm (Silica gel-ODS, 5 μm)	CO_2–CH_3CH_2OH	120 °C, 162 kg cm^{-2}, −1 °C min^{-1}	UV (210 nm)	Mori et al.[41]

Poly(ethylene oxide) [Neodol 23]	$0 < DP < 22$	9 m × 100 μm (BP-10)	110 °C	FID	Chester[13]
Poly(propylene oxide)	$\overline{M}_n$ 425	10 m × 63 μm (DB-1)	120 °C, 120 atm, 1.5 atm min^{-1}	FID	White and Houck[20]
Poly(*t*-butyldimethylsilyl acrylate)	900–10 000	10 m × 50 μm (DB-1)	120 °C, 70 atm, 1 atm min^{-1}	FID, MS	Pinkston et al.[46]

In all examples, the mobile phase is neat carbon dioxide.
DB-1 is a 100% dimethyl-polysiloxane stationary phase.
DB-5 is a 95% dimethyl-(5%)-diphenyl-polysiloxane stationary phase.
SE-54 is a 95% dimethyl-(4%)-diphenyl-(1%)-vinyl-polysiloxane stationary phase.

diethyl ether, or ethanol was also examined for the SFC separation of polystyrene.[26]

However, carbon dioxide is currently the fluid of choice in many SFC applications to polymers because of its low critical temperature (31 °C), nontoxic, nonflammable nature, and lack of interference with most detection methods. The solvent strength of carbon dioxide at a density less than 0.25 g cm^{-3} is less than that of perfluorinated alkanes, while at a density of 0.98 g cm^{-3} it exceeds that of hexane, perhaps approaching the solvent strength of methylene chloride.[15] Addition of polar modifiers to carbon dioxide extends its somewhat limited solvent strength, allowing the SFC separation of nonpolar to medium polar polymers. Alcohols, ethers, acetonitrile, and methylene chloride are suitable for modifiers.

When a polymer sample is chromatographed without the use of gradients, i.e. at constant conditions, the retention times of the members of homologous series will increase exponentially with increasing molecular weight which leads to long overall analysis times. Since this increase of retention time is paralleled by an increase of peak widths, detection limits also increase with increasing molecular weight. For compensation of these effects gradient techniques are applied. In SFC, three types of gradients can be used: temperature gradients, pressure/density gradients, and composition gradients. Furthermore the combinations of these gradient types can be used for improving a separation. The gradients chosen were often linear, although a tendency for crowding of the peaks at the end of the program could often be observed. Most of capillary SFC separations are carried out on a density gradient. The gradient conditions in SFC separation of polymers are discussed extensively in the literature.[19,47]

3.2 Columns and Stationary Phase

SFC may be performed either in packed columns or in open tubular capillary columns. Both approaches have been demonstrated numerous times in the literature. In addition, there are a few examples of polymer separation using a hybridization of the two major column types – packed capillary columns.[48,49] There are advantages and disadvantages to each approach.

Packed columns are advantageous when the goal of the separation is to preparatively isolate individual analytes. The sample capacity of packed columns is much greater than capillary columns. It has also been indicated that packed columns may develop more theoretical plates per unit time than capillary columns, which may be important when speed is an important analytical aspect. Another advantage of packed columns is that packed HPLC columns can be used for packed column SFC. Thus, a wide variety of stationary phases are available in packed column form for which no capillary column counterpart currently exists.

Predominantly, nonpolar polymers have been separated on polar as well as nonpolar stationary phases. With increasing polarity of the analyte polar stationary phases like untreated silica become less useful, and better results are obtained on less polar materials. For packed columns, different types of polar and nonpolar stationary phases other than untreated silica are available and used for SFC separation of polymers, e.g. porous glass beads,[50] alumina,[34] surface-modified silica (C_{18}, CN, NH_2, and Diol)[25,31–34,40,41,51,52] and polystyrene beads.[29,53,54] One problem with silica-based materials is the solubility of silica stationary phases in a polar mobile phase which is only slight in liquid polar organic

media but may be pronounced in supercritical eluents. A polystyrene stationary phase is suitable if the polymer is highly crosslinked which precludes swelling and shrinking and gives the material a stable geometry. For example, 2-vinylpyridine oligomers which had been difficult to separate on silica could successfully be chromatographed on a polystyrene stationary phase.[29] As a general rule, the more specific the interactions between analytes and stationary phase, the higher is the selectivity for separation.

The main advantage of capillary column SFC over packed column SFC is that longer capillary columns can be used. This is due to the low pressure drop and open tubular nature of the capillary. Thus, separations using capillary columns can be performed using a greater number of theoretical plates, i.e. increased efficiency. SFC capillary columns are typically fused silica columns of 50–100 μm internal diameter (ID) coated with a bonded and crosslinked polysiloxane stationary phase.

3.3 Detectors

SFC is compatible with many types of conventional HPLC and GC detectors, such as ultraviolet/visible (UV/VIS)

Figure 2 Capillary SFC chromatogram of poly(dimethylsiloxane) using a synchronized asymptotic density/linear temperature program.[45] Conditions: asymptotic density programmed from 0.19 g mL^{-1} (12 min initial hold time) to 0.495 g mL^{-1} with $t_{1/2} = 20$ min; linear temperature programmed synchronously from 100 °C (12 min initial hold time) to 160 °C at 1 °C min^{-1}. detection and FID. Typically, packed column SFC system is equipped with an UV detector whereas capillary SFC system is equipped with an FID.

Polymers containing an aromatic chromophore can easily be detected by UV absorbance. High-purity carbon dioxide is transparent over the whole UV range down to 190 nm, and thus polyethers which contain only the weak ether chromophore can also be detected by means of an UV detector.[29] For UV detection at short wavelengths, the choice of appropriate mobile phase is important. Carbon dioxide/methanol as well as carbon dioxide/acetonitrile have successfully been used for UV detected SFC separations of PMMA,[29,33,36,53,55,56] poly(caprolactone),[38,53] poly(oxymethylene),[35] and poly(*n*-butyl isocyanate).[39]

FID has been used numerous times as a universal detector for capillary SFC. However, FID is only applicable when a nonflammable mobile phase such as neat carbon dioxide is used. Therefore, applications in the polymer field are limited to the SFC separations of polymers with low polarity such as paraffin waxes[13,24,42,57,58] or polysiloxanes[24,45,47,58–65] (Figure 2) or separations of low molecular weight polymer adducts such as ethoxylated surfactants.[13,47,57,58,66–73]

ELSD looks promising for a quasi-universal detection in SFC. This method is adequately sensitive (>20 ng) and compatible with modifiers. ELSD was successfully used for the packed column SFC separations of poly(oxyethylene)s[31,32,54] (Figure 3).

Carbon dioxide has IR adsorption that completely blanks out the spectrum from 3800–3500 cm^{-1}, 2500–2200 cm^{-1}, and below 800 cm^{-1}. The remaining regions of the IR spectrum are therefore useful for detection purposes. The application of on-line SFC/FTIR with flow cell interfaces was demonstrated for the separation of poly(dimethylsiloxane)[63] and phenyl-ethoxy-acrylate oligomers.[74] Another approach utilizes FTIR as an off-line detector of SFC. In this approach, analytes are collected uncontaminated on an IR transparent window from the outlet of SFC column as the mobile phase evaporates. IR spectra are measured from the deposited spot using an IR microscope.[59,75,76] Excellent SFC/FTIR chromatograms were obtained for poly(oxyethylene)s of average molecular weights 400, 600, 1000, and 1500 (Figure 4).

Much attention has been focused on SFC systems interfaced to MS detection systems.[42,44,70,73,77–83] Aside from being a very sensitive and highly selective detector, the mass spectra are useful for structure elucidation of analytes. Figure 5 shows the total-ion chromatogram obtained from SFC/MS analysis of polybutadiene with average molecular weight of 500.[44] In this analysis, the

Figure 5 Total-ion chromatogram obtained from the SFC/MS analysis of a 500 average-molecular-weight polybutadiene sample.[44] (Reproduced by permission of Wiley-VCH.)

chromatographic effluent from capillary SFC was directly introduced into the MS source. The isobutane chemical ionization yielded a gentle fragmentation process that produced a dominant protonated molecule, $(M + 1)^+$, for each homolog.

Polymer separation by SFC using a fluorescence[84] or ion-mobility detector[67] has also been reported.

4 SUPERCRITICAL FLUID CHROMATOGRAPHY SEPARATIONS OF OLIGOMERS AND LOW-MOLECULAR-WEIGHT POLYMERS

4.1 Determination of Molecular Weight and Molecular Weight Distribution

As illustrated in Figure 1, SFC of polystyrene separates into 18 individual species. Using the chromatogram and assuming that UV absorption is concentration dependent only (no effects due to molecular weight), one can calculate number average ($\overline{M}_n$) and weight average ($\overline{M}_w$) molecular weights for the polystyrene on the basis of Equations (1) and (2):

$$\overline{M}_n = \left(\frac{\sum W_i}{M_i} \right)^{-1} \quad (1)$$

$$\overline{M}_w = \sum W_i M_i \quad (2)$$

where M_i and W_i denote the molecular weight and weight fraction of species i in the polymer. The results ($\overline{M}_n = 576$, $\overline{M}_w = 649$) were in close agreement with the values by other methods including nuclear magnetic resonance (NMR), vapor pressure osmometry (VPO) and SEC.[85] Close agreement between packed-column SFC/UV and SEC/UV was also observed for PMMAs with $\overline{M}_n$ 900–990.[52]

SFC and MS are complementary methods for characterizing low molecular weight polymers. Both capillary SFC/FID and time-of-flight secondary ion mass spectrometry (TOFSIMS) provide well-resolved signal intensities of low molecular weight poly(dimethylsiloxane)s (Figure 6). To determine the achievable accuracy of these independent analytical methods, a direct comparison was performed on poly(dimethylsiloxane)s in the molecular weight range from 1000 to 10 000. Results obtained by SFC/FID and TOFSIMS fit well up to molecular weight 3000 whereas remarkable differences occur for higher molecular weight regions due to mass discrimination effects. These have been found to be more pronounced for SFC than for TOFSIMS.[64]

A systematic investigation was undertaken as to the performance of different analytical methods, including capillary SFC/FID and matrix-assisted laser desorption/ionization (MALDI) TOFMS (time-of-flight mass spectrometry), in the molecular weight determinations of poly(ethylene glycol) with average molecular weight of 300 and poly(propylene glycol) with average molecular weight of 425. The data from all methods (SFC/FID, MALDI/TOFMS, SEC/density, SEC/refractive index (RI), SEC/ELSD, reversed and normal phase HPLC/density, /RI, /ELSD) agreed quite well.[86]

A poly(ethylene oxide)–poly(propylene oxide) block copolymer, $HO(EO)_{n1}(PO)_m(EO)_{n2}OH$, was characterized with respect to molecular weight distribution and block length of the individual blocks using two-dimensional chromatographic techniques. In the first dimension the block copolymer was separated according to the length of the poly(propylene oxide) block by HPLC at the critical point of adsorption. The

Figure 6 (a) SFC chromatogram and (b) TOFSIMS spectrum (positive secondary ions) of a poly(dimethylsiloxane) sample. (Reproduced with permission from Hagenhoff et al.[64] Copyright 1991, American Chemical Society.)

resulting fractions uniform with respect to the number of PO units ($m = 4–10$) were subjected to SFC and the average length $n_1 + n_2$ and the molecular-weight distribution of the poly(ethylene oxide) blocks were determined for every fraction. Because of the high chemical similarity, SFC did not resolve oligomers of the same gross composition but different ethylene oxide distribution, e.g. $HO(EO)_4(PO)_m(EO)_2OH$ and $HO(EO)_3(PO)_m(EO)_3OH$.[87]

Stem length and stem length distribution in the lamellar crystals of natural and synthetic rubbers were determined by the use of SFC. The stem length was detected as the number of isoprene units per molecule of ozonolysis products of the rubber crystals (the ozonolysis under specific conditions selectively decomposes noncrystalline parts in polyisoprene chains). SFC analysis clearly showed that the ozonolysis products (*cis*-1,4-oligoisoprenes) have bimodal distributions centered at 9–11 ($\overline{M}_w/\overline{M}_n < 1.11$) and 23–25 ($\overline{M}_w/\overline{M}_n < 1.03$) isoprene units respectively (Figure 7).[25]

4.2 Separation According to Chemical Structures of Polymers

Separations by SFC yield different retentions for polymer series depending on their end-groups. This was demonstrated for oligo(1,3,6-trioxocane)s with hydroxy or benzoyloxy functionality.[88] The cationic ring-opening polymerization of 1,3,6-trioxocane in the presence of benzyl alcohol results in the formation of α, w-dihydroxy, α-hydroxy-w-benzyloxy, and α, w-dibenzoyloxy oligo(1,3,6-trioxocane)s. In their SFC separation, two to three peaks were obtained for each *DP*. Molecular weight and functionality type distributions in the oligo(1,3,6-trioxocane)s were determined simultaneously from one SFC chromatogram.[89]

Macromonomers and telechelics are known to be oligomers with exactly one or two functional end-groups. An exact knowledge of the macromonomer and telechelic functionality is necessary for the application. SFC was demonstrated to be useful for monitoring the preparation and subsequent reaction of macromonomers from styrene and from 2-vinylnaphthalene; the end-group included epoxy, hydroxy, or diol functionality. SFC separation of the condensation product from diol-functionalized styrene macromonomer (average *DP* of 13) and sebacyl dichloride was also described.[90]

Oligomeric ethylene oxide adducts which are frequently used as nonionic surfactants are produced via ethoxylation of fatty alcohols. When fatty alcohols are of technical grade, they may contain more than only one alcohol; this leads to the formation of parallel oligomer series. The SFC chromatogram of such a product is shown in Figure 8, where two main series, originating from ethoxylation of dodecanol and tridecanol, are seen along with additional series which are present in minor amounts.[13,70] Because oligo(oxyethylene) surfactants are very readily separated by means of capillary SFC/FID using carbon dioxide as the supercritical mobile phase, the separation of this class of compounds has been exemplified in a large number of publications.[13,47,57,58,66–73,91] Characterization of oligoethers has also been performed on packed column SFC.[33,54]

SFC proved to be useful for analyzing cyclic siloxanes in technical silicone oils (low molecular weight poly(dimethylsiloxane)s). Since the preparation of silicone oils with desired properties such as great range of fluidity and low freezing point requires minimization of cyclic components, the determination of cyclic siloxanes in the presence of linear poly(dimethylsiloxane)s is of special importance. Good results were obtained by SFC providing sufficient separation up to a level of molecular weight nearly 6000.[92] Direct coupling of SFC with MS permitted an unambiguous identification of linear and cyclic poly(dimethylsiloxane)s.[93] By means

Figure 8 Pressure-programmed SFC/FID chromatogram of Neodol 23-6.5, an alkyl ethoxylate mixture of the formula $H(CH_2)_n(OCH_2CH_2)_eOH$, where n is 12 or 13 and e varies from 0 to at least 22. Some e values are indicated on the chromatogram. Conditions: carbon dioxide mobile phase; column temperature, 110 °C; BP-10 column, 9 m × 100 μm ID, 0.1 μm thick. (Reprinted from T.L. Chester 'Capillary Supercritical-fluid Chromatography with Flame-ionization Detection: Reduction of Detection Artifacts and Extension of Detectable Molecular Weight Range', *J. Chromatogr.*, **299**, 424–431, Copyright 1984, with permission from Elsevier Science.)

of high-temperature GC substances of high molecular weight do not elute, or they elute with great peak broadening. SEC does not provide the resolution required. SFC thus remains the method of choice for solving the above mentioned analytical problem.

Prepolymers of random novolac and resol resins were separated by SFC according to the number of nuclei (phenol groups) and the number of methylol groups attached to the nuclei.[41] Nine oligomers for novolac resins from dihydroxydiphenylmethanes (dimer, dinuclear) to decanuclear oligomers were separated. Seven isomers of trinuclear novolac oligomers were identified. Molecular weight averages were determined without any calibration standards ($\overline{M}_w = 417$ and $\overline{M}_n = 366$ for the sample examined).

Practical advantages of packed-column SFC over HPLC and GC were shown for the analysis of epoxy resins.[40] Analysis times of bisphenol A diglycidyl ether resins and isocyanuric acid triglycidyl ether resins are reduced by a factor of 4 and 5, respectively, with SFC compared with HPLC. For example, the analysis of isocyanuric acid triglycidyl ether resin by HPLC took 40 min, including 10 min reconditioning time, while a packed column SFC chromatogram with a similar resolution was obtained in 8 min, including 2 min reconditioning time. This allowed the use of SFC as an on-line analyzer in a pilot plant to monitor the end of the epoxidation reaction in isocyanuric acid triglycidyl ether.

SFC and SFE were reviewed with references as techniques for analyzing surface coatings and many of the raw materials that go into their manufacture.[94] Reactive oligomeric mixtures such as radiation curing coatings, polyisocyanate curing agents, and surface active agents were separated using capillary SFC with carbon dioxide. Polar oligomeric mixtures such as epoxy, vinyl, and phenol–formaldehyde resins were separated with modified mobile phases on packed column SFC.

4.3 Fractionation of Individual Polymer Homologs

One of the important features of packed column SFC is its use for the separation on a preparative scale, i.e. on a scale which allows us to utilize the fractions further or characterize the fractions by physical-chemical methods. Though the scale-up of SFC in a laboratory may be limited to some extent (≤10–20 mm ID columns) for safety reasons, several tens to hundreds of milligrams of purified fractions can easily be obtained by repeated SFC fractionations. When carbon dioxide is the chosen eluent, preparative SFC has practical advantages of the ease of fraction collection and the simple nature of the solute in the collected state. For example, a simple depressurization of supercritical carbon dioxide drastically reduces its solvating power and the purified sample precipitates.

Fractionation of polymers into the individual homologs by packed column SFC was first demonstrated for the separation of polystyrene with $\overline{M}_n$ of 578. Lower molecular weight fractions were taken and rechromatographed under the same SFC conditions to prove their purity.[2] An instrument for fraction collection was devised.[95] The research for polystyrene fractionation was extended to the isolation of 15 individual homologs from the 1mer to 15mer by the use of pentane–methanol (9 : 1) as the supercritical mobile phase and a 5 mm ID × 6 m column packed with porous silica gel (particle size 37–75 μm); more than 11 h was required for each chromatographic run. The combined amounts of the fractions after 16 consecutive runs ranged from 6 to 20 mg. MS analysis of each fraction was reported.[5,6]

Early efforts for polymer fractionation include the separation of an oligosiloxane (DC-710) which is used as a stationary phase in GC. The separation was optimized on an analytical scale[9] and then carried out on a preparative scale. The separated compounds were investigated with respect to their properties as a stationary phase for GC.[10]

Recent developments in SFC apparatus and packing materials have made it possible to carry out the fractionation in a much shorter time with improved

separation.[23] The applicability of this method to the fractionation of polymer homologs has been enhanced further by the great progress in polymerization chemistry which provides a variety of polymers with controlled molecular weight and well-defined chain structure. This is because the preparation of polymers suitable for SFC separation is essential for effective fractionation of each individual homolog.

Highly isotactic (*it*-) and highly syndiotactic (*st*-) PMMAs prepared by stereospecific living polymerizations were fractionated by the SFC using carbon dioxide containing ethanol or methanol as the mobile phase and a 10 mm ID × 250 mm column packed with nonbonded silica gel (particle size 5 μm, pore size 100 Å). Negative temperature gradients, which increase the density of mobile phase, were applied at a constant fluid-pressure of 200 kg cm^{-2}. Depending on the $\overline{M}_n$ of polymer, 20 to 50 mg was able to be separated in a chromatographic run.[36,55,56] Though the separation was achieved also by the use of ODS-treated silica gel as the stationary phase,[52] nonbonded silica gel was superior in a loadable amount of sample.

Figure 9(a) shows an SFC trace of *it*-PMMA with $\overline{M}_n$ of 4100.[36] Small amounts of authentic samples of the *it*-22mer and *it*-28mer were added to the PMMA as the internal standard. The purified *it*-50mer gave a single peak in a chromatogram recorded under the same conditions (Figure 9b), indicating the uniformity with respect to the number of repeating units in a molecule. Optimization of the operating conditions for SFC made it possible to separate *it*-PMMA with an $\overline{M}_n$ as large as 6650 (Figure 10a). Each individual homolog from 80mer ($C_{404}H_{650}O_{160}$ = 8068) to 100mer ($C_{504}H_{810}O_{200}$ = 10 070) was isolated. The molecular weight of *it*-100mer was confirmed by MALDI/TOFMS.[23,56]

Figure 9 SFC chromatograms of (a) isotactic PMMA (DP = 40.8, $\overline{M}_w/\overline{M}_n$ = 1.12, containing the authentic samples of the 22 and 28mer) and (b) the 50mer isolated from (a).[36] (Reproduced by permission of The Society of Polymer Science, Japan.)

Figure 10 SFC chromatograms of (a) isotactic PMMA ($\overline{M}_n$ = 6.7 × 10^3, $\overline{M}_w/\overline{M}_n$ = 1.07) and (b) the 100mer isolated from (a). Authentic 45-mer was added to the PMMA as an internal standard. Column, Develosil 100-5 (10 mm ID × 250 mm); mobile phase, carbon dioxide–methanol (81 : 19); flow rate, 14.8 mL min^{-1}; initial temperature, 80 °C; temperature, −0.5 °C min^{-1}; pressure, 235 bar. (Reprinted from K. Ute,[23] 349–368, by courtesy of Marcel Dekker Inc.)

The series of purified homologs of *it*- and *st*-PMMAs were useful for the studies of molecular weight dependence of glass transition temperature (T_g) and melting temperature (T_m).[96] Because each homolog is uniform (perfectly monodisperse) with respect to molecular weight, it showed higher T_g and higher degree of crystallinity than nonuniform *it*- or *st*-PMMA with the corresponding (average) molecular weight. Uniform PMMAs with definite molecular weights also served as reference materials for polymer analysis and characterization, e.g. molecular weight standards for SEC[36,56] and MALDI/TOFMS.[97]

SFC is sensitive to the stereostructure of polymer homologs. When a mixture of *it*- and *st*-24mers was subjected to the SFC, *it*-24mer eluted faster than *st*-24mer.[55] The elution order was reversed in the SFC separation on ODS-treated silica gel.[52] The SFC separation according to stereostructure was applied to the fractionation of mixtures of *it*-, *st*-, and stereoblock PMMAs with uniform molecular weights (Figure 11).[98,99]

Low molecular weight poly(D-lactic acid) prepared by the living ring-opening polymerization of D-lactide with Al[OCH(CH$_3$)$_2$] in toluene was fractionated by packed column SFC (Figure 12a).[23] Slight degradation of polymer chain occurred in the SFC separations at above 65 °C. In spite of the fact that the poly(D-lactic acid) was prepared from the cyclic dimer (D-lactide), the polymer consisted of the homologs with both even and odd numbers of repeating units. The formation of odd homologs clearly indicates that

Figure 11 SFC chromatograms of a reaction mixture of hydroxyl-terminated isotactic and syndiotactic 46mers of methyl methacrylate and sebacoyl dichloride and of block PMMAs isolated from the mixture.[98] Methanol, 3.0 mL min^{-1}; carbon dioxide, 7.0 mL min^{-1}; initial temperature, 85 °C; rate of cooling, 2 °C min^{-1}. (Reproduced by permission of The Society of Polymer Science, Japan.)

the polymerization accompanies intermolecular and/or intramolecular transesterification of polymer chains. SFC analysis of poly(D-lactic acid) prepared with *N*,*N*-bis(salicylidene)ethylenediiminoaluminum methoxide [(salen)AlOCH$_3$], however, revealed that the polymer contained only a small amount of odd homologs (Figure 12b). The uniform poly(D-lactic acid)s obtained by SFC fractionation were highly crystalline. The 9mer ($C_{30}H_{44}O_{19} = 708.7$) gave thin-needle crystals from a solution in ethanol. Specific rotation, $[\alpha]_D$, of the uniform poly(D-lactic acid)s in chloroform increased with increasing number of repeating units toward an asymptotic limit which was practically reached at $DP \approx 20$. The $[\alpha]_D$ of 20mer was almost comparable to the value for high molecular weight poly(D-lactic acid) (+151°).

SFC fractionations of poly(ε-caprolactone) and poly(δ-valerolactone) were carried out and the 26mer, 28mer, and 30mer were isolated in pure form. These uniform polymers were analyzed by electrospray and MALDI/TOFMS. Molecular-weight dependences of their T_g and T_m were also reported.[38]

Polyisocyanates have received a great deal of attention due to their chiroptical properties arising from stiff helical conformation of the polymer chain. The living polymerization of *n*-butyl isocyanate was initiated with $TiCl_3OCH_2CF_3$ and terminated with acetic anhydride. Poly(*n*-butyl isocyanate) with the chain structure $CF_3CH_2O(CONC_4H_9)_nCOCH_3$ was obtained. The acetyl end-capping is necessary because low molecular weight

Figure 12 SFC chromatograms of poly(D-lactic acid)s prepared by polymerization with (a) Al[OCH(CH$_3$)]$_3$ and (b) (salen)AlOCH$_3$. Column, Develosil 100-5 (10 mm ID × 250 mm); mobile phase, carbon dioxide–ethanol (a) 97 : 3 (initial) → 90 : 10 (15 min), (b) 90 : 10 (initial) → 85 : 15 (20 min); flow rate, 10 mL min^{-1}; temperature, (a) 65 °C, (b) 55 °C; pressure, 198 bar. (Reprinted from K. Ute,[23] 349–368, by courtesy of Marcel Dekker Inc.)

polyisocyanates with the −NH terminus in the polymer chain readily decompose to cyclic trimers (isocyanurates) under the packed column SFC conditions. The acetyl-endcapped poly(*n*-butyl isocyanate) ($\overline{M}_n = 3970$, $\overline{M}_w/\overline{M}_n = 1.20$) was separated into the uniform polymers from 15mer to 55mer by means of SFC using carbon dioxide/ethanol as the mobile phase at 90 °C and 200 bar (Figure 13).[39] Single crystals were grown from an ethanol solution of the 12mer ($C_{64}H_{113}O_{14}N_{12}F_3 = 1131.7$) and subjected to X-ray crystallographic determination. The backbone of the polyisocyanate chain adopted an 8/3 helix with a repeat distance of 15.6 Å. This chain structure agreed well with the results of X-ray diffraction studies on powder samples and oriented films of high molecular weight poly(*n*-butyl isocyanate). The molecular weight dependence of chiroptical properties of uniform poly(*n*-butyl isocyanate)s in solution were investigated.[23]

In the middle of the 1920s, Staudinger et al. (see Ute et al.[35]) fractionated oligo(oxymethylene) diacetate,

Figure 13 SFC chromatogram of the CF_3CH_2O-initiated, acetyl-terminated oligo(*n*-butyl isocyanate).[39] An authentic sample of the 15mer was added to the oligomer as an internal standard. Chromatographic conditions: Develosil 100-5 (10 mm ID × 250 mm); carbon dioxide–ethanol, 85 : 15 (initial), 70 : 30 (25 min); flow rate, 10 mL min^{-1}; temperature, 90 °C; pressure, 20 MPa. (Reproduced by permission of The Society of Polymer Science, Japan.)

$CH_3CO_2(CH_2O)_nCOCH_3$, into the individual homologs from 1mer to 26mer by rectification and fractional crystallization. These studies provided the basis for the formulation of many concepts essential in macromolecular science. Recently, purely uniform oligo(oxymethylene) diacetates that can be isolated as single crystals have been obtained by SFC fractionation.[35] During the separation, thermal degradation of the substrate occurred slightly (~3%). Each uniform oligo(oxymethylene) homolog showed a sharp melting endotherm. The melting points were significantly higher than those reported in the literature, which demonstrates improved purity of the uniform oligo(oxymethylene) diacetates obtained by the SFC fractionation. The crystal structures determined for the 9mer to 13mer were interesting as models of crystal polymorphysm in high molecular weight poly(oxymethylene).[23,35]

5 SUPERCRITICAL FLUID CHROMATOGRAPHY SEPARATIONS OF HIGH MOLECULAR WEIGHT POLYMERS

5.1 Separation of Polymers by Supercritical Fluid Chromatography in the Adsorption Mode

As described above, SFC has mostly been used by polymer chemists in adsorption chromatography mode to separate oligomers or low molecular weight polymers into their individual molecular species. For high molecular weight polymers, the peaks of the individual members of the homologous series can no longer be separated and give only one, more or less broad peak for the whole sample. The shape and broadness of this peak reflects the molecular-weight distribution of the polymer sample.

Figure 14(a) shows a chromatogram of a mixture of six polystyrene samples, each having relatively narrow molecular weight distribution and $\overline{M}_w$ ranging from 3600 to 600 000. The individual polystyrenes are well resolved from each other. This separation was achieved by the adsorption mode SFC using pentane/1,4-dioxane eluent system and nonbonded silica stationary phase.[27] A proper choice of gradient conditions is essential for this type of separation; the solvent strength must be increased to elute higher molecular weight polymers. In another chromatogram (not shown here), standard polystyrenes with close molecular weight averages ($\overline{M}_w$ = 93 000 and 111 000) were separated almost completely. A comparison of Figure 14(b) with Figure 14(a) shows a very broad molecular weight distribution of an industrial polystyrene ($\overline{M}_w$ = 230 000) which, in addition, is multimodal.

Figure 14 (a) SFC chromatogram of a polystyrene mixture; initial column end pressure: 185 bar. (b) SFC chromatogram of an industrial polystyrene sample; initial column end pressure: 182 bar.[27] Eluents, pentane–1,4-dioxane; sample solvent, 1,4-dioxane; column, 250 mm, ID 4.6 mm, packed with LiChrosorb Si 100, 10 µm; detector, UV, 254 nm; oven temperature, 250 °C; flow rate, 1 mL min^{-1}; (——) detector signal; (- - - -) content of 1,4-dioxane in the eluent mixture (% v/v); S, sample solvent peak; $\overline{M}_w$, 3600 (1), 10 000 (2), 53 700 (4), 93 000 (5), 254 000 (7), 600 000 (9). Commun.*, **24**, 142–144, Copyright 1983, with permission from Elsevier Science.)

5.2 Size-exclusion Chromatography using Supercritical Mobile Phase

Separations according to the size-exclusion mechanism are very popular in liquid chromatography (LC) of polymers. In SEC, elution order is reversed with the adsorption chromatography; the large molecules appear first at the outlet of the column, followed by the smaller molecules in the order of their decreasing size. The use of supercritical fluid in place of liquids for SEC was suggested and first demonstrated in 1977 for polystyrenes up to molecular weight 4000 by using a 40 Å porous silica stationary phase and 1,1-difluoroethane compressed above 1000 kg cm^{-2}.[11] Because the supercritical state is characterized by lower viscosity and faster diffusion than liquids both the resolution and speed of separation would be enhanced. This expectation was confirmed by the separation of standard polystyrenes with SEC using supercritical dichloromethane and pore glass packing (86 Å mean pore size).[100] Figure 15 shows the chromatographic performance derived from liquid and supercritical fluid SEC for separations of three polystyrene samples and benzene. The resolution of higher molecular weight polystyrenes is better in the supercritical case. It was also suggested that the effective dimension or size of polystyrene is smaller in supercritical fluids than in the corresponding liquids.

As an approach closely related to supercritical SEC, "enhanced-fluidity SEC" was proposed recently. An enhanced-fluidity liquid is prepared by mixing a low viscosity liquid, usually liquid carbon dioxide, with a common organic solvent. The use of enhanced-fluidity mixtures of tetrahydrofuran (THF)–liquid carbon dioxide for the SEC separation of standard polystyrenes under room temperature and moderate pressure conditions was investigated.[101,102] Mixtures of up to 40 mol% carbon dioxide with THF resulted in a significant drop in mobile-phase viscosity, without a decrease in solvent strength. As a result, higher efficiency and a shorter analysis time were obtained. Adsorption effects began to play a role at carbon dioxide concentrations above 50 mol%.

Figure 15 Comparison between (a) supercritical fluid and (b) liquid SEC.[100] 1, MW 110 000 polystyrene (0.3 wt%); 2, MW 17 000 polystyrene (0.8 wt%); 3, MW 4000 polystyrene (0.6 wt%); 4, benzene (0.4 wt%). SFC conditions: column pressure, 320 kg cm^{-2}; column temperature, 224 °C; mobile phase flow rate, 630 μL min^{-1}. LC conditions: mobile phase flow rate, 630 μL min^{-1}; column temperature, 25 °C. 5.3 Separation of Polymers by Supercritical Fluid Chromatography at the Critical Adsorption Point

LC at the critical adsorption point (CAP) is a chromatographic method that allows the separation based upon chemical heterogeneities of polymers.[103] Operating at "critical" conditions where size-exclusion effects are balanced by adsorption effects, retention becomes independent of the length of the polymer chain and separation is accomplished exclusively by the chemical heterogeneities of polymers, for example end-groups or branching. This principle can be applied in SFC.

Figure 16 shows the SFC/CAP chromatograms of polystyrene precursor ($\overline{M}_w = 2000$) and the functionalized polystyrenes, synthesized by reaction of the living polystyrene precursor with a trifunctional core compound 2,4,6-trichloro-1,3,5-triazine.[104] The mobile phase was a mixture of 79% dichloromethane and 21% carbon dioxide by volume. The length of arms corresponds to the size of the initial precursor. Separations of hydroxyl- as well as acetyl-terminated polystyrenes could be achieved. The main peak indicates the polystyrene precursor, whereas the following peaks are caused respectively by the hydroxyl and acetyl end-groups of the polystyrene molecules with increasing number of arms.

Finding the exact experimental conditions for the CAP is often a matter of trial and error. In SFC, the determination of the CAP is possible by varying the mobile phase (carbon dioxide mixed with a polar solvent) or the temperature, pressure, and density of the fluid, respectively. The unique benefits of using supercritical fluid for the chromatography at the CAP may be similar to those described for the enhanced-fluidity chromatography at the CAP.[105] The high compressibility of enhanced-fluidity liquid mixtures allows precise and broad ranging control of solvent strength. The optimum method to approach the CAP is to roughly approach by varying the eluent composition, and then precisely determine the critical condition by changing the eluent pressure. The application of enhanced-fluidity chromatography at the CAP was illustrated for the characterization of copolymers of styrene and methyl acrylate.

Just and Much[104] provided a comprehensive analysis of the use of supercritical mobile phases in three

Figure 16 Separation of (a) polystyrene precursor, (b) OH-terminated three-armed polystyrene, and (c) acetyl-terminated three-armed polystyrene at critical conditions of adsorption in SFC.[104] Mobile phase: dichloromethane–carbon dioxide (79 : 21, v/v); temperature, 473 K; pressure, 200 bar. (Reproduced by permission of Gordon and Breach Science Publishers.)

separation modes: adsorption chromatography for the separation of oligomers, SEC for the determination of molecular weight distributions, and adsorption chromatography at critical conditions for the determination of functionality type. The authors provided examples of these modes with separations of polystyrenes.

6 ANALYSIS OF COMMON POLYMER ADDITIVES BY SUPERCRITICAL FLUID CHROMATOGRAPHY

Polymer additives are found in plastics, rubbers, surfactants, textiles, and cosmetics. They are usually added at very low amounts (0.01–1.0%) to polymeric materials to protect them against deterioration during processing at high temperature and/or to improve their aging characteristics. There is a practical need for analytical methods to characterize additives and to determine their concentration in the polymers. In an increasing number of publications including review articles,[40,94,106] the unique performance of SFC and SFE for determination of polymer additives has been mentioned.

A standard mixture of 21 polymer additives (UV stabilizers, antioxidants, metal deactivators, and slip agents) varying in polarity and molecular weight from 225 to 1178 was separated into the individual components by SFC on a nonpolar capillary column with carbon dioxide as the mobile phase and was analyzed by an FTIR detector coupled to the column outlet. Good quality spectra were obtained from samples at levels of the order of 100 ng. A polypropylene extract was analyzed to demonstrate the method and to show the limitation of using retention time data for identifying unknown compounds.[107]

HPLC and SFC separations were compared for characterization of more than 15 polymer additives in polyolefin extracts. Detection in HPLC was by ELSD or RI, in SFC by ELSD and FID. SFC was found to be more universally applicable to these compounds than HPLC. SFC was also superior in terms of both resolution and speed of analysis.[108]

SFE as a powerful technique to eliminate solvent or matrix effects before chromatographic analysis was combined with packed column SFC for determination of polymer additives in various types of polymers. Low-density polyethylene was extracted and analyzed with on-line SFE/SFC with good yields for some of the common polymer additives. The calculated levels of the additives were in good agreement with the assayed values from the polymer manufacturer.[109,110] A procedure to quantitatively analyze additives in various polyethylene and polypropylene samples using on-line SFE/SFC was also described.[111] Either oligomers or polymer additives were selectively extracted depending on the pressure. In other studies, organotin stabilizers and plasticizers in poly(vinyl chloride)[112,113] and polymer additives in polystyrene[110] was analyzed by on-line SFE/SFC.

ABBREVIATIONS AND ACRONYMS

CAP	Critical Adsorption Point
DP	Degree of Polymerization
ELSD	Evaporative Light Scattering Detector
FID	Flame Ionization Detection
FTIR	Fourier Transform Infrared
GC	Gas Chromatography
HPLC	High-performance Liquid Chromatography
ID	Internal Diameter
IR	Infrared
LC	Liquid Chromatography
MALDI	Matrix-assisted Laser Desorption/Ionization
MS	Mass Spectrometry

NMR	Nuclear Magnetic Resonance
ODS	Octadecylsilane
PMMA	Poly(methyl methacrylate)
RI	Refractive Index
SEC	Size-exclusion Chromatography
SFC	Supercritical Fluid Chromatography
SFE	Supercritical Fluid Extraction
T_g	Glass Transition Temperature
T_m	Melting Temperature
THF	Tetrahydrofuran
TOFMS	Time-of-flight Mass Spectrometry
TOFSIMS	Time-of-flight Secondary Ion Mass Spectrometry
UV	Ultraviolet
UV/VIS	Ultraviolet/Visible
VPO	Vapor Pressure Osmometry

Adhesion of polymeric materials to various substrates, from metals to glass to other polymers, is a subject that continues to grow in importance, with today's technologies. The biocompatibility of polymer-based implantable devices and prostheses is largely determined by the tendency of the material surfaces to be 'wetted' or adhered to by proteins. Surface and interfacial energy relationships determine in large part whether the adhesive and adherend achieve the intimacy of molecular contact that is a requisite for good adhesion. An aspect of the behavior of polymer blends and of block copolymers is that, depending on the relative surface energy of the components, and on the phase morphology and chain mobility, lower energy components may segregate to the surface to the detriment of interfacial adhesion, or perhaps promoting heterophase nucleation. There are numerous both technological and scientific motivations for the characterization of polymer surface energy.

The objective in surface energy measurement is to characterize the free energy of a solid or a liquid surface (or, in general, an interface). The surface free energy per unit area (or surface tension) of polymers is a fundamental property. It may be measured in the solid, liquid, or solution state, but perhaps most often the intention is to refer the measured value to the solid state. Hence, one approach involves measuring the surface tension of polymer melts and low molecular weight liquid polymers by conventional methods and using one of several equations to extrapolate to values for the polymer in the solid state.

Methods for determining the surface energy of solid polymers usually involve measuring the contact angle of a sessile liquid drop, and this methodology will be discussed in some detail. A relatively new technique for direct polymer surface energy measurement based on Johnson, Kendall, Roberts (JKR) (contact mechanics) theory will be discussed.

1 INTRODUCTION

An *interface* is a part of a multi-component system, where the physicochemical parameters of the system undergo continuous change from the bulk properties of one component to the other. If one of the system components is air or vacuum, the interface becomes a *surface*. By definition, the *surface energy* γ is the work that must be done to create a unit of surface area. Hence, for a closed system [Equation 1]:

$$\gamma = \left(\frac{\partial G}{\partial A}\right)_{T,P} \tag{1}$$

where G is the Gibbs free energy of the total system and A is the surface area. If the work spent to create the surface is reversible, surface energy may be called surface tension. The terms 'surface tension' and 'surface energy' are often used interchangeably. However, this article deals in general with polymers and rubbers, which on a reasonable timescale are typically solid at normal temperatures and pressures. Since the process of creation of the surface of a solid is often irreversible, the more general term surface energy will be more applicable.

For the same reason, methods for the measurement of the surface energy of liquids that are based on

Encyclopedia of Analytical Chemistry
R.A. Meyers (Ed.) Copyright © John Wiley & Sons Ltd

the reversible creation of surface are impossible to implement for solids. The process of surface creation for polymers and rubbers in the solid state will involve a significant amount of energy spent irreversibly on various viscoelastic processes. Therefore, indirect methods of surface energy determination must be used.

2 SURFACE ENERGY OF POLYMERIC MATERIALS

Several methods for surface energy determination of polymers have been developed. They generally consist of two main approaches: (1) various extrapolation methods and (2) wetting methods based on Young's equation. Recently, determination of surface energy based on JKR theory by direct measurements of molecular adhesion has been reported. Most of these methods will be described here, with more attention given to those that produce most consistent and reliable results.

2.1 Extrapolation Methods

Surface energies of solid polymers may be obtained by measuring the surface tensions of polymers in a liquid state followed by extrapolation of the data to the surface energy of a solid. Variations of molecular weight and the temperature can be used to obtain a set of polymer samples in a liquid state (bearing in mind that surface tension is an increasing function of molecular weight). Conventional methods for measuring the surface tension of a liquid are then employed to obtain γ vs T or γ vs molecular weight relations. These relations are then used to extrapolate to the surface energy of a solid polymer.[1] Both of these extrapolation methods produce accurate results. On the other hand, extrapolation from concentration dependence, which is performed by dissolving the polymer in a solvent, may not give an accurate estimate because of possible solvent segregation effects.

2.1.1 Temperature Dependence Method

Like the surface tension of the low molecular weight liquids, the surface tension of polymers decreases with increase in temperature. For most polymers the surface tension will vary linearly over the normal temperature range (0–200 °C). Therefore, if the dependence of surface tension on temperature for a given polymer is measured experimentally at temperatures where the polymer is in the melt state, such data could be used to extrapolate surface tension to the lower temperature, at which the polymer will be solid. Figure 1 shows the typical dependence of surface tension on temperature for six different polymers from Roe.[2] Table 1 lists the values of surface tension γ at 150 °C and the extrapolated value for 20 °C. Detailed descriptions of experimental apparatus for measuring the surface tension of molten polymers are available in the literature.[2] The standard pendant drop technique is used and surface tension is calculated from the shape of the drop. The method of calculation is identical with that employed to obtain the surface tension of low molecular weight liquids. However, since the viscosity of most polymer melts is relatively high, long times (30 min–1 h) might be necessary for the drop to attain the equilibrium shape.

In general, during the analysis of these kinds of data, one should keep in mind that primary and secondary phase transitions may affect the extrapolated surface

Figure 1 Surface tension values obtained from six polymer samples. Open triangles, poly(ethylene oxide) (Carbowax 600); filled circles, linear polyethylene (Alathon 7050); open squares, branched polyethylene (Bakelite DYLT); filled triangles, polyisobutylene (Oronite 128); open circles, polypropylene (atactic fraction); filled squares, polydimethylsiloxane (Dow Corning silicone 200 fluids), 106 and 6x104 cSt. [Reprinted with permission from R.-J. Roe, *J. Phys. Chem.*, **72**(6), 2013–2017 (1968). Copyright 1968, American Chemical Society.]

Table 1 Surface tension data for various polymer melts, extrapolated to solid state by Macleod's method. [Reprinted with permission from R.-J. Roe, *J. Phys. Chem.*, **72**(6), 2013–2017 (1968). Copyright 1968, American Chemical Society.]

Polymer	γ at 150 °C (dyn cm^{-1})	γ at 20 °C (extrapolated), (dyn cm^{-1})	$-d\gamma/dT$ at 150 °C	Macleod's exponent
Poly(ethylene oxide)	33.0	42.8	0.076	3.0
Linear polyethylene	28.1	35.6	0.058	3.2
Branched polyethylene	26.5	34.8	0.064	3.3
Polybutene	25.1	34.0	0.066	4.1
Polypropylene	22.1	29.4	0.056	3.2
Polydimethylsiloxane	13.6	20.4	0.048	3.5

energy of a polymer. Macleod's equation[3] could be used to analyze quantitatively the effects of melting and glass transitions on polymer surface energy. Although this equation was initially developed for small-molecule liquids, Wu[1,4] and Roe[5] have shown that it could also be applied to polymers. Macleod's equation is usually written as Equation (2):

$$\gamma = \gamma^0 \rho^n \tag{2}$$

where ρ is the density and γ^0 and n are positive, temperature-independent constants. For polymers, n usually varies from 3.0 to 4.4 (see Table 1). Macleod's equation is essentially an acknowledgement of the fact that variation of the surface energy with temperature is due to variations in density.

The analysis of Macleod's equation according to Wu[6] shows that above the glass transition temperature there should be a slight decrease in the slope of the plot of surface tension versus temperature. However, for most polymers this effect of second-order transitions on the surface tension–temperature dependence can often be neglected and the linear extrapolation method can still be used.

First-order transitions generally have a more pronounced effect on the surface energy of polymers and cannot be discounted. The accuracy of surface energy extrapolated from temperature dependence data depends on the degree of crystallinity of the actual polymer surface in question. For polymers that possess some degree of bulk crystallinity, the temperature dependence method could still work since such polymers are usually covered by an amorphous surface layer. This happens because the amorphous phase is less dense than the crystalline phase, and therefore it has lower surface energy. However, various degrees of surface crystallinity can be induced by casting the polymer against certain molds or by surface-localized mechanical stresses. Some high-energy mold surfaces were found to nucleate polyethylene, resulting in formation of transcrystalline surfaces, whereas low-energy mold surfaces gave amorphous polymer surfaces.[7,8]
